In 1983, the virus responsible for the newly identified human acquired immunodeficiency syndrome (AIDS) was described by several investigators worldwide. It was initially called human lymphotropic virus III or lymphadenopathy-associated virus, but further identification revealed the syndrome was caused by a single novel virus renamed HIV. Two species of HIV (i.e., HIV-1 and HIV-2) were later identified. Both are lentiviruses responsible for the development of AIDS, but transmission patterns, demographics, and disease progression are different. HIV-2 is closely related to simian immunodeficiency virus (SIV) and is not responsible for pediatric HIV disease because it has lower rates of

mother-to-child transmission (MTCT) and a very protracted disease course. HIV-1 is responsible for pediatric disease.

HIV infection continues to be one of the world's most serious health and development challenges. An estimated 36.7 million people worldwide are living with HIV/AIDS.²⁶⁹ Of these, 1.8 million are children younger than 15 years.²⁶⁹ Every year, approximately 2.1 million people acquire HIV infection, including 150,000 children, most of whom were infected perinatally and live in sub-Saharan Africa²⁶⁹ (Fig. 192B.1).

Despite significant advances in prevention, diagnosis, and treatment of HIV infection, most of those living with or at risk for HIV infection

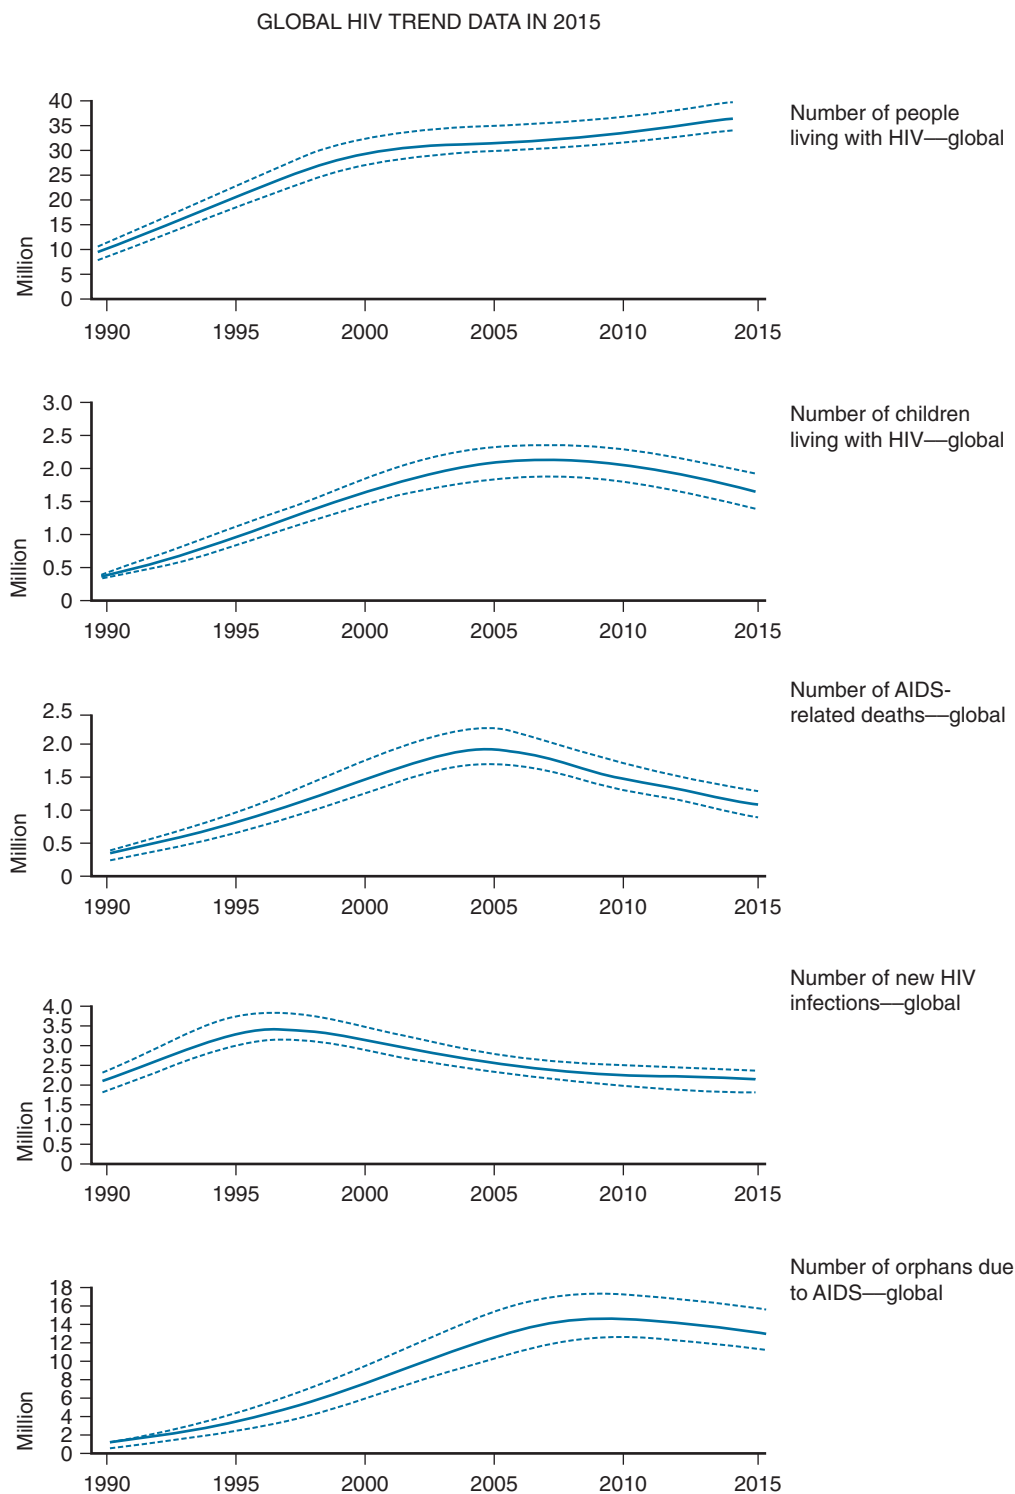

FIG. 192B.1 Global statistics for HIV infection. (From UNAIDS. AIDS by the numbers—AIDS is not over, but it can be. <http://www.unaids.org/en/resources/documents/2016/AIDS-by-the-numbers>.)

do not have access to prevention and appropriate treatment. It is estimated that only 54% of people with HIV infection are aware of their HIV infection status.²⁸⁸ Sub-Saharan Africa has almost two thirds of the global total of incident HIV infections, for an estimated total of 25.6 million infected people in the region.²⁸⁸ An estimated 35 million people have died of AIDS since the start of the epidemic, including 1.1 million in 2015.²⁸⁸

Despite the sobering statistics, global efforts in the past decade have been successful in reducing HIV prevalence rates worldwide, and the number of incident infections has declined. The number of people with HIV receiving treatment globally increased, from 7.5 million in 2010 to 17 million by the end of 2015.²⁷⁰ In the absence of a successful vaccine, the recognition that treatment of infected individuals significantly reduces sexual transmission of the virus⁵⁹ has created the treatment for prevention paradigm. Observational and modeling studies have demonstrated the dramatic impact global antiretroviral treatment can have on curtailing the epidemic.^{108,210} The use of preexposure prophylaxis (PREP) has been highly beneficial in protecting against new infections,^{45,110} and much progress has been made in preventing MTCT. An estimated 77% of pregnant women with HIV worldwide had access to antiretroviral treatment to prevent infection of their babies in 2015, and perinatal infections have declined by more than 50% since 2010.²⁷¹

Renewed optimism that a functional cure for HIV may be obtainable followed reports such as the successful transplantation of CCR5-Δ32/Δ32-deleted stem cells to suppress viremia in an individual with HIV infection,¹²⁷ the Mississippi baby who had a prolonged period of HIV aviremia while off antiretrovirals after very early initiation of antiretroviral therapy,¹⁶¹ or the Visconti trial participants who remained aviremic off antiretroviral therapy after early treatment initiation.²³⁷ Despite some progress, much work still needs to be done to reduce basic health disparities that favor HIV spread even in developed countries such as the United States.²⁷¹

Research continues to demonstrate that racial and ethnic disparities in health are often a marker of a range of broader social and economic challenges. Eradicating racial disparities and preventing HIV infections in the changing face of the US and global epidemic will be the medical and public health challenges for this century.³⁶

DEFINITION AND STAGING OF PEDIATRIC HIV INFECTION

The natural history of pediatric HIV-1 infection is bimodal.²⁴³ Studies conducted in developed countries before the availability of antiretrovirals demonstrate that approximately 20% of children exhibit very rapid disease progression with rapid loss of CD4⁺ cell counts and development of AIDS-defining conditions before 2 years of age.²⁰³ Approximately 60% to 65% of HIV-infected children have intermediate disease progression, with the appearance of AIDS-defining events by 7 to 8 years of age in the absence of treatment. As in adults, there is a small subset of children (≈5%) who have very slow to no disease progression by 8 years of age. These children enter adolescence with minimal or no symptoms of HIV disease. Studies conducted in Africa demonstrated a faster pace of disease progression, with most pediatric patients having AIDS-defining conditions by 5 years of age.²⁰¹ This may reflect the higher overall burden of disease and multiple coinfections.

Antiretroviral treatment makes it possible to alter the natural history of HIV disease and transform disease progressors into nonprogressors. This translates into improvements in the quality of life and reduction

in HIV-associated disease morbidity and mortality. In this context, current staging of HIV disease does not carry the same implications as in the early 1990s because immune preservation and immune reconstitution supported by continuous antiretroviral treatment allow children with advanced immunodeficiency to regenerate their immune system and revert from full-blown AIDS to an asymptomatic disease presentation.

From a historical perspective, pediatric AIDS was first reported to the Centers for Disease Control and Prevention (CDC) in 1982; AIDS was first reported in adults in 1981.³⁵ The first definitions of pediatric AIDS were published in 1985. In 1994 and again in 2008, the classification system was revised to include more advanced viral diagnostic technology and a system for staging pediatric HIV disease that involved clinical and immunologic axes.^{40,187}

Table 192B.1 outlines the clinical axis of the staging system, which is composed of four clinical categories: N, A, B, and C.¹⁸⁷ The clinical axis was originally intended for unidirectional use for an individual child. Severity of disease proceeds from category N (i.e., asymptomatic), to A (i.e., mildly symptomatic), to B (i.e., moderately symptomatic), to C (i.e., severely symptomatic), and then to HIV-associated death. Clinical category C describes children with AIDS-defining characteristics (i.e., wasting, encephalopathy, opportunistic infections, and malignancies), but it excludes lymphoid interstitial pneumonitis or pulmonary lymphoid hyperplasia (LIP/PLH). Clinical category B describes children with other specific HIV-associated illnesses (e.g., single episodes of bacteremia, leiomyosarcomas, lymphoproliferative lung disorders, anemia, thrombocytopenia) and excludes children with a clinical category C event. Clinical category A describes children with two or more specific HIV-associated illnesses (i.e., lymphadenopathy; hepatomegaly; splenomegaly; upper respiratory tract infections, sinusitis, or otitis media; parotitis; and dermatitis) and excludes children with a clinical category C or B event. Clinical category N describes children without clinical category C, B, or A events; these children may or may not be completely asymptomatic (i.e., single category A events such as lymphadenopathy may exist).

Tables 192B.2 and 192B.3 provide expanded descriptions of the immunologic axis of the staging system. They include categories 1 (no evidence of immune suppression), 2 (moderate immunosuppression), and 3 (severe immunosuppression).¹⁸⁷

In resource-limited settings, the World Health Organization (WHO) staging system has been implemented as a guide to describe the severity of HIV-related symptoms in children with disease classifications ranging from 1 to 4, with 1 being asymptomatic and 4 corresponding to AIDS.²⁹⁰

EPIDEMIOLOGY AND TRANSMISSION AND PREVENTION

Transmission by Blood Products

Documented spread of pediatric HIV infection has occurred through blood and blood products, perinatal transfer from mothers with identified risk factors, breast milk,⁷⁹ and sexual transmission to children and adolescents.⁹⁹ Most adolescents are infected through sexual exposure and frequently are unaware of their HIV status, which renders them good candidates for early intervention studies.³ Since HIV screening techniques, including nucleic acid amplification testing of pooled blood products, were adapted and recombinant factor products were increasingly used, transmission of HIV by blood products has been rare in the United States.⁷²

TABLE 192B.1 Factors Affecting Intrapartum and In Utero Transmission of HIV

Viral Transmission	Immune Transmission	Maternal Transmission	Fetal Transmission
Virus load	Decreased CD4 ⁺ count	Advanced disease	Prematurity
Virus phenotype/ tropism	Maternal neutralizing antibodies	Primary infection during pregnancy	Chorioamnionitis
Virus genotype	Cell-mediated immunity Mucosal immunity	Coinfection Twins: higher risk for first born Timing of infection Obstetric events	Infant immune response

TABLE 192B.2 Clinical Categories of Pediatric HIV Classification

Immunologic Category	CLINICAL CATEGORIES			
	N: No Signs or Symptoms	A: Mild Signs or Symptoms	B: Moderate Signs or Symptoms	C: Severe Signs or Symptoms
1. No evidence of suppression	N1	A1	B1	C1
2. Evidence of moderate suppression	N2	A2	B2	C2
3. Severe suppression	N3	A3	B3	C3

TABLE 192B.3 Immunologic Categories Based on Age-Specific CD4⁺ T-Lymphocyte Counts and Percentage of Total Lymphocytes

Immunologic Category	AGE OF CHILD					
	<12 mo		1–5 y		6–12 y	
	μL	%	μL	%	μL	%
1. No evidence of suppression	≥ 1500	≥ 25	≥ 1000	≥ 25	≥ 500	≥ 25
2. Evidence of moderate suppression	750–1499	15–24	500–999	15–24	200–499	15–24
3. Severe suppression	<750	<15	<500	<15	<200	<15

Modified from Mofenson LM, Brady MT, Danner SP, et al. Guidelines for the prevention and treatment of opportunistic infections among HIV-exposed and HIV-infected children: recommendations from CDC, the National Institutes of Health, the HIV Medicine Association of the Infectious Diseases Society of America, the Pediatric Infectious Diseases Society, and the American Academy of Pediatrics. *MMWR Recomm Rep.* 2009;58(RR-11):1–166.

Perinatal Transmission

In the absence of interventions to curtail MTCT of HIV-1, HIV-1 infection among children parallels that of women of childbearing age. Perinatal transmission of HIV-1 accounts for most worldwide cases of pediatric HIV-1 infection, with the exception of adolescent acquisition of HIV-1 via adult risk behaviors. HIV-1 transmission from mother to child occurs in 25% to 30% of cases when there is no maternal antiretroviral treatment,^{200,244} and if breastfeeding until 12 months of age is included, the transmission risk can be as high as 40%. Infection can be transmitted during pregnancy, at the time of labor and delivery, and through breastfeeding.

Worldwide, approximately 2000 HIV-exposed infants are born daily, with 90% of cases occurring in sub-Saharan Africa.¹⁷⁴ Breastfeeding transmission contributes another 240,000 infant infections per year.²⁷³ Although combination antiretroviral therapy (cART) can reduce MTCT transmission to less than 1% in developed countries,⁷⁵ failure to recognize HIV-1 infection in women and unavailability of treatment contribute to continuing MTCT of HIV worldwide. Management of HIV-1 infection must consider early diagnosis of infection, the natural history of HIV-1 infection in children and surrogate markers of disease, suitable pediatric drug formulations, drug metabolism and pharmacokinetics of antiretrovirals in children, and the paucity of pediatric treatment data compared with that for adults.

Acquisition of HIV infection can occur in utero, during the intrapartum period, or through breastfeeding. Even before antiretroviral treatment was recommended to pregnant women, two thirds of HIV-exposed infants escaped HIV infection. Perinatal HIV infection rates have declined substantially in the developed world since 1994, following publication of the landmark PACTG 076 study, which demonstrated reduction of perinatal HIV transmission in women who used zidovudine in pregnancy compared with placebo.⁶¹ Approximately 30% to 50% of infants who contract HIV infection acquire it in utero, and 50% to 70% acquire the infection during the intrapartum period.^{32,71,178}

To characterize the timing of HIV infection, a working definition was created for acquisition of infection in utero and intrapartum.²⁶ An infant is considered to have in utero infection if virologic tests (i.e., HIV DNA or RNA polymerase chain reaction [PCR] assays) are positive within 48 hours of life. Due to the risk of contamination with maternal blood, cord blood samples should not be used for diagnostic evaluations.

Infants are considered to have intrapartum HIV infection if diagnostic tests within the first 48 hours of life are negative but further virologic testing after 1 week of life is positive. There is evidence that most cases of HIV transmission occur late in pregnancy or at delivery.

Infants with in utero infection appear to have a more rapid disease course compared with infants with intrapartum HIV infection.⁷⁰ In utero infected infants have normal CD4⁺ cell values at birth and are usually born with a low virus load (as measured by DNA or RNA PCR).¹⁷⁷ Infants infected by HIV in utero are asymptomatic at birth. In utero HIV infection appears to result from transplacental passage of virus or ascending viral infection in patients with prolonged rupture of membranes.¹⁸³ In the animal model, researchers demonstrated that viral infection of the amniotic fluid with SIV resulted in infection of all offspring.²⁷⁶

Intrapartum transmission of HIV infection is responsible for most perinatal cases. In a prospective study of 271 HIV-infected infants using HIV DNA PCR, 38% of children were found to be positive for HIV within 48 hours of life, 93% were positive by 14 days of age, and 96% were positive by 4 weeks of age.⁷⁸ A few infants may not have detectable virus as late as 3 months after delivery. Untreated infants tend to maintain a very high virus burden throughout their first year of life, and immunologic patterns of primary viremia in infants have been described.¹⁶⁰ High-level viremia can persist for a longer period in infants than in adults with primary infection; untreated early infection is associated with a high risk of death.²⁷⁹ Before the advent of combination antiretroviral therapy, discordant twin infections were reported, with the first-born twin having a higher risk of infection.⁷⁷

Postpartum transmission of HIV through breastfeeding has been a continuing problem for the prevention of HIV MTCT efforts worldwide. HIV-1 can be transmitted as a cell-associated or cell-free virus in breast milk.¹⁶⁵ Mastitis, which triggers migration of inflammatory cells, is also a known risk factor for HIV transmission by breast milk,²⁴⁸ as is nonexclusive breastfeeding⁶³ or oral thrush in the infant.²²⁶ Longer duration of breastfeeding is another risk factor for transmission,¹² as is maternal primary infection during lactation.¹⁹² However, in areas where safe alternatives to breastfeeding are not available, formula feeding is associated with higher morbidity and mortality rates.

Provision of combination antiretroviral therapy to lactating, HIV-infected mothers has significantly increased HIV-free survival of infants and produced improved infant outcomes in terms of growth and reduced

rates of infections.^{169–171} Successful screening of pregnant women with availability of antiretroviral treatment for HIV-infected pregnant and lactating women through the WHO B and B+ program¹²⁸ has decreased early and late postpartum HIV transmission through breastfeeding in recent years.

Early diagnosis of HIV-1 infection is crucial for identification of at-risk infants and initiation of treatment. All HIV-1–exposed infants carry maternal HIV-1 antibodies until approximately 15 to 18 months of age. Early pediatric diagnosis relies on identification of the virus by HIV-1 DNA or RNA PCR techniques. The former technique measures integrated virus in the host genome, and the latter method measures circulating plasma virus. HIV-1 coculture is not routinely performed because of cost and time, although it is also a reliable diagnostic method. Infants infected in utero usually have positive PCR results within the first 48 hours of birth, whereas infants infected at the time of labor and delivery can have a negative HIV DNA or RNA PCR result at birth, followed by a positive result 1 week to 2 months after birth. Because breastfed infants have continuing HIV-1 exposure, they can develop a positive HIV DNA or RNA PCR result at any time. The risk of breastfeeding transmission by an HIV-1–positive mother is approximately 16%.⁹¹ Repeat PCR testing in the first few months of life is required to determine the timing of infection, and the sensitivity of PCR results increase over time in the absence of breastfeeding.^{79,202}

In the United States, the total annual number of AIDS cases resulting from perinatal transmission peaked in 1992, with slightly fewer than 1000 newly affected children reported.²¹ Predominance of perinatal transmission is found worldwide, especially in countries where adult heterosexual transmission is uniquely prevalent (e.g., Africa).^{44,236} Before the use of perinatal antiretroviral interventions, the reported transmission rate for perinatally acquired HIV infection was between 12% and 25% in the United States and Europe and higher in Africa.^{61,263}

Maternal risk factors associated with enhanced perinatal HIV transmission and identified through national surveillance of reported AIDS cases include untreated HIV disease, seroconversion during pregnancy or breastfeeding, drug abuse, heterosexual infection by sexual partners with risk factors for acquiring HIV disease, and maternal transfusion before 1985. Prospective and retrospective evaluations of maternal predictors for perinatal HIV transmission have been the focus of many studies. Maternal transmission predictors identified include maternal viremia (i.e., measured by quantitative HIV RNA PCR or viral load),^{93,166} maternal immunosuppression, an inadequate immune response (i.e., measured by the CD4⁺ T-cell count and neutralizing antibody production),¹⁶⁶ and viral characteristics (e.g., chemokine receptor tropism, resistance patterns of maternal virus at delivery or infant virus at birth).²³⁹

Pregnancy and placental variables (e.g., delivery mode, duration of rupture of membranes, chorioamnionitis) can influence the risk of perinatal transmission of HIV.^{196,257,262} Infant variables evaluated as predictors of transmission of HIV include specific human leukocyte antigen (HLA) markers and the infant cellular immune response (e.g., cytokine production, activated T-cell function).^{83,162,166,220} Immunogenetic factors (e.g., chemokine coreceptor expression) may confer protection against progression of disease.²⁴⁶

Advances in perinatal primary antiretroviral therapy, such as antepartum, peripartum, and postpartum administration of zidovudine in nonbreastfeeding HIV-infected women without severe immunosuppression in the United States, led to a decrease in perinatal transmission rates. The CDC estimated that the number of infants born annually with HIV in the United States decreased from 1650 in 1991 to 100 to 200 in 2004, which remained the number reported in 2016.

The provision of antiretrovirals to infants born to HIV-infected mothers as prophylaxis has been standard of care in the United States since 1994, when results of the Pediatric AIDS Clinical Trials Group study 076 were published.⁶¹ The study demonstrated that zidovudine administered to the mother starting at 16 weeks' gestation, accompanied by an intravenous zidovudine infusion during labor and delivery and followed by four times daily dosing of zidovudine to the infant from birth to 6 weeks of age, was highly effective in preventing HIV MTCT compared with placebo (8% vs. 25%, $P < .001$). In developed countries, infants are provided 4 to 6 weeks of zidovudine starting at birth and

given at 2 mg/kg per dose four times daily or 4 mg/kg per dose twice daily as the standard of care.²¹⁴

The major toxicities of zidovudine prophylaxis for infants include anemia and neutropenia, but the effects are dose dependent and self-limited, tend to occur toward the end of the course of treatment, and rarely require interruption of prophylaxis.¹⁴⁷ In resource-limited settings, single-dose nevirapine (2 mg/kg) given to the infant shortly after birth is the standard of care and has been implemented in multiple studies after publication of the HIVNET 012 results,¹¹⁵ which documented the efficacy of this approach in reducing MTCT when associated with single-dose nevirapine given to the mother at the time of labor. Among HIV-infected infants whose mothers were not treated with antiretrovirals throughout the course of pregnancy and are therefore at higher risk for HIV acquisition, double antiretroviral prophylaxis initiated within 48 hours of birth with three doses of nevirapine in the first week of life concurrently with 6 weeks of zidovudine is more effective for the prevention of HIV intrapartum infection than zidovudine alone.²⁰⁴

An equally efficacious alternative regimen is the use of lamivudine and nelfinavir in the first 2 weeks of life concurrent with 6 weeks of zidovudine.²⁰⁴ Due to the lack of availability of pediatric formulations of nelfinavir, the nevirapine plus zidovudine combination is preferable.²¹⁴ A lopinavir plus ritonavir suspension is not recommended by the US Food and Drug Administration (FDA) for use in infants younger than 2 weeks of age. In resource-limited settings, the use of daily nevirapine prophylaxis for HIV-exposed infants for the prevention of MTCT has been evaluated for those up to 6 months of age and shown to be effective and safe in the prevention of postpartum HIV acquisition.⁶² However, most settings in sub-Saharan Africa have transitioned to the WHO program options B or B+, which recommend treatment with cART to all HIV-infected women during pregnancy and lactation or from pregnancy onward with no further treatment interruption.²⁸⁹

The selection of antiretroviral therapy to reduce perinatal HIV transmission must consider optimal treatment for infected pregnant women and the potential for fetal harm. Maternal factors include the mother's viral load, degree of immunosuppression, medications for use in treatment of comorbid conditions (e.g., tuberculosis, hepatitis C virus infection), and the potential for inducing viral resistance. Transmission of treatment-resistant HIV to infants has been described in the literature, but it occurs infrequently.

Other considerations to prevent perinatal transmission of HIV include scheduled delivery to minimize prolonged rupture of membranes, including a recommendation from the American College of Obstetrics and Gynecology for scheduled cesarean section for women with viral loads exceeding HIV RNA levels of 1000 copies/mL.⁶⁰ In a meta-analysis of 15 North American and European cohorts of HIV-infected pregnant women ($n = 100$ women), there was a 5% difference in vertical transmission rates for those with scheduled delivery by cesarean section (2% transmission rate) compared with those with other delivery modes (7.3% transmission rate).²⁶² Evaluation of the morbidity and mortality related to scheduled cesarean sections suggests that HIV-infected pregnant women may have a higher incidence of postpartum hemorrhage with resultant transfusion, sepsis, pneumonia, and death than their noninfected pregnant peers undergoing the same scheduled procedure (odds ratio, 1.6).¹⁵⁹ HIV-infected pregnant women without detectable viral loads should be informed preoperatively about the risk of morbidity related to cesarean section performed to prevent perinatal HIV transmission.

Sexual Transmission: Second Wave of Pediatric AIDS

In the adult, young adult, and adolescent populations, sexual acquisition of HIV infection is the predominant transmission pattern. The intersection of pediatric sexual abuse and transmission of HIV has been reported. Sexual abuse of young children and infants may be associated with the transmission of sexual disease (e.g., syphilis, gonorrhea, human papillomavirus). HIV infection should be considered in the differential diagnosis of sexually transmitted diseases in children assessed for sexual assault. In contrast to the infrequent reports of sexual transmission to infants and children younger than 13 years, adolescents are infected frequently by sexual transmission. In an inner-city urban US community, 41% of sexually active female youth described having vaginal intercourse

and receptive anal intercourse in casual relationships.¹²⁴ Use of condoms was reported by 64% of youth, but receptive anal intercourse was used by some as a form of contraception, and condom use in this setting was reported in only 41% of these encounters.

The American Academy of Pediatrics (AAP) stressed the importance of preadolescent and adolescent care and encouraged performing examinations of patients who are 11 to 14 years of age. Health care providers can take advantage of these preteen and teen visits as an opportunity to explore sexual exposures of youth in their care and to educate sexually active youth on options for contraception.

Because the symptom-free period for clinical expression of HIV infection in adolescents may approach adult standards (>10 years), many young adults 20 to 29 years of age with AIDS probably became infected with HIV during adolescence. Adolescents with AIDS, like affected infants and children, are more likely to be poor and black or Hispanic. Reported risks of transmission to adolescents vary by age, sex, and race or ethnicity. Behavioral transmission (i.e., men who have sex with men and heterosexual contact) and transmission of unknown risk predominate as reported risk behaviors of US youth.²⁸⁷ The category of heterosexual contact accounts for the largest proportional increase in the reported risk of transmission for female and male adolescent cases of AIDS. The nature of youth (e.g., experimentation, search for self and sexual identity, inability to access health care easily) places adolescents at risk for heterosexual transmission of HIV infection.²⁸³

Recommendations for postexposure prophylaxis for nonoccupational exposure to blood, genital, or other body fluids were updated by the CDC in 2016.⁴⁷ After exposure to these fluids from an HIV-infected individual and with determination of significant exposure risk, a 28-day regimen of combination antiretrovirals (many containing integrase inhibitors) is recommended if administration can begin within 72 hours of exposure.

Other Modes of Transmission

Less frequently reported transmission routes of HIV infection are important for pediatric health care providers to acknowledge and target. The risk of HIV transmission through breastfeeding is reported infrequently in the United States. In a study of HIV-infected, breastfeeding mothers and their exposed infants, Dunn and associates⁷⁹ documented a 14% risk of HIV transmission through breastfeeding above the established perinatal transmission risk. Study results prompted the adoption of guidelines for preventing transmission by this route by avoiding breastfeeding by HIV-seropositive mothers in the United States. Transmission of HIV to infants by breastfeeding represents approximately one half of all perinatal transmission worldwide, and the risk of transmission continues with prolonged breastfeeding after the first year of life.¹⁴³

Children may be prone to needlestick or sharps injuries that occur in a nonhospital, nonmedical setting, such as needlestick injury associated with inappropriately discarded needles in public places such as public parks and bathrooms. Recommendations for psychological support, discussion of adherence to prescribed medications, and toxicity monitoring are provided by the AAP Committee on Pediatric AIDS.¹¹⁹

An estimated 13% of 159 diagnoses of HIV and AIDS among children younger than 13 years were attributed to modes other than perinatal transmission. In 2008, a study of three pediatric HIV cases concluded that premastication was the likely route of HIV transmission through blood in saliva.⁹⁸ A cross-sectional survey conducted by the CDC in nine pediatric HIV clinics in the United States indicated that among primary caregivers of children 6 months of age or older, 31% of the 154 reported the children received premasticated food from themselves or someone else. Although data on the risk of HIV transmission by premastication are limited, the CDC recommends that HIV-infected caregivers not premasticate food for HIV-uninfected children.³⁷ Health care providers should routinely inquire about premastication of foods fed to infants, instruct HIV-infected caregivers to avoid this practice, and advise patients about safer feeding options.

No data have suggested that HIV infection is transmitted casually from HIV-infected children to siblings, playmates, or caregivers.²⁵⁵ Documentation of transmission routes and lack of casual transmission have prompted defining appropriate measures for mainstreaming of HIV-infected children and families.⁷⁴ This measure includes school,

childcare, and foster care and adoption placement for HIV-infected children, and it promotes social incorporation of the children.

ETIOLOGY

Identification of the origin of AIDS followed closely behind the clinical description of this complex immunodeficiency. In 1983, investigators worldwide identified a viral cause for AIDS and described human lymphotropic virus III, lymphadenopathy-associated virus, and a virus associated with persistent generalized lymphadenopathy.^{56,92} These viruses subsequently were identified as similar and were called HIV.⁶⁴ Two species of HIV are recognized: HIV-1 and HIV-2. HIV-1 has been the more prevalent pathogenic species and, especially in the United States, almost uniformly has been associated with reported AIDS cases.

Viral divergence is common, and HIV-1 can be divided into three groups: M, major; O, outliers; and N, non-M/non-O. The M group represents the major group, with subtypes (i.e., clades) showing significant symmetry.¹¹⁶ The major subtypes have been identified, and data from the WHO HIV Vaccine Initiative identified clade C in 50% of global infections in 2004.¹¹⁶ Clade B is identified most frequently in industrialized countries, including the United States. In 2004, recombinant subtypes were responsible for 18% of worldwide infections. Continued collection of data is important for the successful development of a vaccine that can be applied universally to stem transmission of HIV. A detailed description of these RNA viruses, their method of viral introduction into the affected host, and their impact on critical immune components is provided in Chapter 192A.

PATHOGENESIS

The Developing Immune System

HIV affects almost all immune cell types and alters their ability to produce important chemokines and interleukins that are integral to immunologic homeostasis.⁵³ Independent of cell damage, the host response can vary according to individual genetic HLA representation and predict probability of infection occurring after exposure or progression of disease.⁸⁵ CD4⁺ T cells bear a receptor (i.e., the CD4⁺ T-cell molecule itself) for the gp120 component of the HIV virion coat, and viral entry into the host cell takes place through this mechanism. Entry does not occur in isolation, and host expression of a chemokine receptor (i.e., CXCR4 for T-lymphotropic HIV strains and CCR5 for monocytopathic HIV strains) interacts in promoting viral particle binding to the host cell membrane and release of viral particles into the cytoplasm.⁵⁵ Heterozygous allele expression of these coreceptors affects expression and progression of HIV disease. Density expression of CCR5 molecules in infants has been correlated with progression of disease even in the presence of antiretroviral therapy and with the slope of CD4⁺ T-cell decline from birth.¹⁰⁰

After infection, the infant with perinatal transmission exhibits a quick rise in detectable HIV viral load that can exceed 750,000 copies/mL in the first weeks or months of life and that persists unchecked without institution of antiviral therapy through the first years of life.² The persistent and lengthy viremia in early perinatal HIV infection is different from acute HIV-1 infection in adults, in which viremia initially may be equally elevated but abates with host immunologic response (albeit without complete elimination) over the course of weeks to months. These distinctions in host response reflect the more ineffective infant immunologic host response to HIV infection.

Proposed mechanisms of immune dysfunction associated with continued viremia in infants include thymic damage with thymocyte depletion, disruption of thymic architecture, early CD4⁺ T-cell depletion that affects the CD8⁺ cell response to HIV antigens, early lymphocyte activation as measured by CD8⁺DR⁺CD38⁺ T cells that impede effective host T-cell response, and genetic predisposition to allow enhanced HIV entry into host cells.^{238,292} Most clinicians opt for early treatment of HIV-infected infants younger than 1 year of age, independent of the clinical or immunologic (i.e., CD4⁺ T-cell count) presentation. Studies have documented that early therapy slows immune system destruction and preserves immune function, preventing clinical disease progression.⁵²

Immune Dysfunction

Abnormalities in adult HIV infection include leukopenia, lymphopenia, and decreased CD4⁺ helper-inducer T cells with an expanded CD8⁺ T-cell population, which results in an inverted CD4/CD8 ratio, typically less than 1.0. Early in the course of infection, T-lymphocyte function is diminished (<50%), with decreased *in vitro* responses to soluble antigens preceding CD4⁺ T-cell depletion. Proinflammatory cytokines appear to induce viral replication by activating the host cell.⁵⁸ HIV-infected CD4⁺ T cells release soluble interleukin-2 (IL-2) receptors. The elevated serum IL-2 receptor levels block cell-bound IL-2 receptors by competition for IL-2. The CD8⁺ T-cell response to HIV-specific antigens is impaired.²⁰⁹

Children with HIV infection seldom are lymphopenic in terms of the values observed in adults. If lymphopenia is observed in children with HIV infection, it usually is seen in older children or in children who have progressed to end-stage HIV disease. CD4⁺ T-cell counts in HIV-infected children commonly exceed 400 cells/mm³. In infants 12 to 24 months of age, a CD4⁺ T-cell value of less than 1000 cells/mm³ is significant for selective HIV-related CD4⁺ T-cell depletion. In infants younger than 12 months, a value of less than 1500 cells/mm³ similarly applies.

After administration of highly active antiretroviral therapy (HAART), T-cell function against specific HIV antigens continues to be imperfect. Despite lowering of viral load, CD4⁺ T-cell depletion may not be completely restored for many weeks. Differential restoration of subpopulations of CD4⁺ T cells (i.e., effector memory cells more commonly encountered than naïve cells) may occur. In 643 children with significant CD4⁺ depletion (i.e., CD4⁺ T cells <250 cells/mm³) and viremia, HAART resulted in a median rise of the CD4⁺ T-cell count of 100 cells/mm³ over the course of 2 years, but anergy was reported in 80%, lack of proliferative response to the specific antigen of tetanus in 73%, and impaired serologic response to hepatitis A virus vaccination in 54%.¹⁵¹ Despite administration of antiretroviral therapy, T-cell immune restoration may not be complete in all affected children.

B-cell dysfunction is similarly identified in HIV-infected adults and children and manifests as hypergammaglobulinemia. HIV-infected adults also demonstrate circulating immune complexes and production of autoantibodies due to polyclonal activation of B cells by HIV itself or concomitant viral infection with cytomegalovirus (CMV) or Epstein-Barr virus (EBV).¹⁴⁸ Immunoglobulin G (IgG) levels may rise to 2 to 3 standard deviations above the mean of normal values, and serum IgA, IgM, and IgE levels also may be elevated. This extreme hypergammaglobulinemia in children may be caused by polyclonal stimulation of B cells by HIV or coinfection with CMV or EBV, or it may be caused by the absence of normal CD4⁺ T-cell immunoregulatory cells. Specific antibody functions measured as childhood vaccine responses often are abnormal and are not always completely restored in the most severely immunocompromised individuals after administration of HAART therapy.¹⁵¹

Other host defense cells affected by HIV infection include natural killer (NK) cells.^{7,245} In adults with chronic HIV infection, reported NK cell abnormalities include differential representation of certain NK cell subpopulations, downregulation of NK ligand expression that affects cytotoxicity of HIV-infected cells, and NK cell–dendritic cell (DC) interactions. Human DCs have myeloid and plasmacytoid subsets. Both subsets have additional roles in HIV infection that lead to viral elimination or control.⁶ Activated myeloid DCs produce cytokines such as IL-12, IL-15, and IL-18. IL-12 is critical for myeloid DCs to induce helper T-cell type 1 (Th1) responses, which promote the potent cytotoxic T-lymphocyte responses that are necessary for clearing virus-infected cells.¹⁴⁹ Plasmacytoid DCs produce more type I interferons (IFNs) in response to HIV than any other cell in the body; they stimulate myeloid DCs in a bystander fashion and directly activate NK cells.²³¹ The implications of these events underlie the need to develop vaccine strategies that enhance the ability of DCs to prime potent T-cell responses that can subvert the potential inhibitory effects of HIV on the immune system.

Monocytes and macrophages play important roles in the pathogenesis of HIV infection by serving as reservoirs of HIV. Defective chemotaxis and bacterial killing have been observed in HIV-infected monocytes

and macrophages, as has defective induction of IL-1, which possibly accounts for the decreased IL-2 response in CD4⁺ T cells.²⁹¹

The immune system also seems to contribute directly to HIV-induced encephalopathy.^{25,123} HIV-induced encephalopathy is particularly devastating in young infants, who fail to reach early motor milestones or, worse, regress from acquired early development. The incomplete state of myelination of central nervous system (CNS) tissue may account for susceptibility to the neurologic effects of HIV infection.

In adults with progression of disease, depletion of CD4⁺ T cells has been linked to shifts in coreceptor use (from CXCR4 to CCR5), and individuals with more severe disease appear to harbor predominantly CCR5-dependent (R5) viral strains.¹⁰³ HIV-containing monocytes are thought to transport HIV into the CNS and infect microglial cells, including astrocytes.⁵⁶ Also implicated in HIV-associated neurologic complications are glial soluble factors that may have a direct neurotoxic effect.¹⁴⁶ Cytokines and reactive oxygen species released by HIV-infected lymphocytes and macrophages in the CNS may damage exposed nerve tissue.²⁸⁰ The normal CNS immune defense system can attempt to enhance neuronal survival.

T-Cell Depletion

Loss of T cells in HIV infection occurs by direct lysis of T cells, apoptosis, and autophagy. Direct T-cell lysis is the result of massive destruction of T cells, as exemplified by the significant lysis of T cells in the gastrointestinal tract early in HIV infection. Almost all T cells are destroyed. The CD4⁺ T-cell number drops precipitously at this time and frequently confirms the clinical suspicion of HIV infection, which is then diagnosed by laboratory testing. Activation of cytokine inflammatory cytokine pathways plays an important role in cell destruction.

Apoptosis is a well-known phenomenon of programmed cell death in HIV infection. Several hypotheses have been offered to explain the mechanism of apoptosis, including a viral cytopathic effect, bystander effect from HIV-infected neighbor cells, death of HIV effector cells migrating into HIV-infected tissue sites, activation of co-proapoptotic signaling on immune cells due to chronic immune activation, and destruction of HIV-infected cells by immune effector cells. Older HIV-infected patients exhibit syncytial formation by interaction on HIV viral proteins and their receptors on neighboring cells. These cells undergo apoptosis by a FAS-dependent pathway.¹²⁰

Autophagy can be considered a form of autophagocytosis in which cytoplasmic organelles are lysed by lysosomes and histone deacetylase. Common regulating factors, such as tumor necrosis factor–related apoptosis-inducing-ligand (TRAIL), serve as stimuli for autophagy in uninfected CD4 T cells through the T-cell receptor for HIV gp120.³⁰

Investigators hypothesize that HIV first depletes mucosal CCR5⁺CD4⁺ effector memory cells, leaving short-lived central memory or naïve CD4⁺ T cells and other immunoregulatory cells in a chronic state of activation that leads to an ineffective host response.^{69,113} Infection of CCR5⁺CD4⁺ effector memory cells also is associated with higher expression of cytotoxic T-lymphocyte-associated protein 4 (CTLA4 or CD152), a potent negative regulator for CD4⁺ T cells.²⁹⁴ High expression of CTLA4 can interrupt IL-2 production by CD4⁺ T cells, impeding the ability of these cells to proliferate and depleting the population. The resultant chronic immune activation may lead to disorganization of the host immune response and further deplete CD4⁺ T-cell regeneration. For patients with the most profound CD4⁺ T-cell depletion, reduction of viral load with antiviral agents does not immediately result in correction of their immune defects.¹⁰³ The study of immune reconstitution with HAART may illuminate the immunopathogenesis of HIV infection.

CLINICAL MANIFESTATIONS

In children and adults, HIV infection causes a spectrum of clinical abnormalities that affect multiple organ systems and include the symptom constellation of AIDS. **Box 192B.1** lists the pre-HAART frequency of AIDS-defining events per 100 child-years.¹⁸⁸

Infection with HIV, independent of a diagnosis of AIDS, can be attended by nonspecific clinical findings, including mild failure to thrive, hepatosplenomegaly, acquired microcephaly, parotitis, generalized lymphadenopathy, nonspecific intermittent diarrhea, intermittent fever,

BOX 192B.1 Frequency of Opportunistic Infections in HIV-Infected Children Before Widespread Use of Highly Active Antiretroviral Therapy (HAART)

Pre-HAART Era (Event Rates >1/100 Child-Years)

Candidiasis
Disseminated *Mycobacterium avium* complex
Serious bacterial infections (e.g., pneumonia)
Herpes zoster
Pneumocystis jiroveci pneumonia
Serious bacterial infections (pneumonia)

Pre-HAART Era (Event Rates <1/100 Child-Years)

Cryptosporidiosis
Cytomegalovirus disease
Systemic fungal disease
Tuberculosis
Toxoplasmosis

Modified from Mofenson LM, Oleske J, Serchuck L, et al. Treating opportunistic infections among HIV-exposed and infected children: recommendations from CDC, the National Institutes of Health, and the Infectious Diseases Society of America. *MMWR Recomm Rep* 2004;53:1–92.

and chronic skin disease. These clinical symptoms are shared by other pediatric disease processes and can, when manifested singly in an HIV-infected host, delay establishing the diagnosis. However, a careful and detailed history should provide insight into potential HIV risk factors and prompt inclusion of HIV infection in the differential diagnosis. With the use of HAART, HIV infection has become a chronic disease and new clinical disease manifestations (e.g., lipodystrophy, hyperlipidemia) that are most closely related to chronic antiviral use have been described.

The health of HIV-infected children has improved during the past decade. Kourtis and associates reported a dramatic decrease (71%) in the number of hospitalizations of children with HIV infection who were 18 years of age or younger between 1994 (before HAART) and 2004 (after HAART).¹⁴²

Opportunistic Infections

Opportunistic infections plague HIV-infected individuals and are the most prominent cause of morbidity and mortality in this cohort. Before the use of HAART, opportunistic infections in children usually were primary infections rather than the reactivation of infection seen in adults.¹⁸⁸ The introduction of effective HAART with associated host immune restoration significantly modified the expression of certain opportunistic infections in adults and children.²⁵⁹ Among children, the overall incidence of these infections declined from 14.4 cases per 100 patient-years before 1997 to 1.1 cases per 100 patient-years.¹⁹⁹ In pre-HAART years, the age at clinical presentation was much younger, and an age younger than 3 years was associated with very rapid CD4⁺ cell decline. Although the number of these opportunistic diseases has diminished, their prevalence appears to be unaffected. The administration of combination HIV therapy, including protease inhibitors (PIs) in adults and children, has improved the survival of perinatally infected children.¹⁰⁴

Pneumocystis Pneumonia

P. jiroveci pneumonia (PJP) is the opportunistic infection most commonly reported for HIV-infected children. Declines in the incidence of PJP have been documented, with rates of 5.8 cases per 100 patient-years reported before 1997 and 0.3 cases per 100 patient-years reported after 1997.¹⁹⁹ PJP has a fulminant course in the pediatric population, with the highest mortality rates for affected children younger than 1 year of age. In a study of 172 children with perinatal HIV infection without HIV-specific intervention, 9% had PJP when they were younger than 1 year, with a median survival of 1 month.

FIG. 192B.2 The classic, diffuse interstitial infiltrates of acute and fatal pneumonia due to infection with *Pneumocystis jiroveci* are seen in a 15-month-old child with perinatal acquired immunodeficiency syndrome. (From Hanson IC. Respiratory infections in HIV-infected children. *Immunol Allergy Clin North Am.* 1993;13:205–17.)

Clinical expression of pediatric PJP often can be distinguished from other pulmonary diseases by the severity of the hypoxemia (i.e., higher alveolar-arterial oxygen gradients), elevated serum lactate dehydrogenase levels, the rapidity of progression of disease with tachypnea and fever, characteristic diffuse interstitial infiltrates on radiography, and the usual lack of digital clubbing.¹¹⁷ The more insidious manifestations of PJP characteristic of HIV-infected adults, such as prolonged fever (>7 weeks), cough, and dyspnea (averaging 3 weeks), less commonly occur in infants and children.

Radiographically, pediatric PJP is associated with diffuse interstitial markings progressing to the white-out pattern of adult respiratory distress syndrome (Fig. 192B.2).¹¹⁸ However, PJP can be seen initially as a unilateral streaky pneumonic infiltrate, as lobar consolidation, or with accompanying pleural effusions.

Aggressive diagnostic measures may be indicated to establish a diagnosis of PJP. Bronchoscopic alveolar lavage (BAL) is the preferred diagnostic tool for adults and children and should be considered a first choice for presumed PJP in children who cannot provide sputum specimens for evaluation. In older children and adults, evaluation of sputum for the presence of *Pneumocystis* with appropriate stains or monoclonal antibodies may preempt the need for using invasive diagnostic measures. PCR assays have been developed for diagnostic evaluation of PJP that are usually more sensitive but less specific than microscopic methods.¹²⁵ Lung biopsy carries the highest sensitivity for identifying the organism but has attendant morbidity related to thoracotomy or video-assisted thoracoscopy (VATS) and placement of a chest tube.

Acute PJP is treated with parenteral trimethoprim-sulfamethoxazole (TMP-SMX) or pentamidine or atovaquone for patients with TMP-SMX or pentamidine hypersensitivity. TMP-SMX treatment consists of 15 to 20 mg/kg per day of the TMP component delivered intravenously three to four times daily. Adjunctive corticosteroid therapy given early for moderate to severe PJP provides significant benefit with only limited evidence of concomitant immune suppression and attendant infectious complications.^{95,256} Concomitant CMV and PJP has been documented in HIV-infected children. For the clinical situation of concomitant viral infection, no existing data recommend delay of corticosteroid use. Treatment of PJP should not be altered. Dosing regimens for corticosteroids are published and include options for use of oral prednisone or oral methylprednisolone or intravenous methylprednisolone.⁴²

After the occurrence of PJP infection, secondary PJP prophylaxis (i.e., therapy initiated after acute disease treatment and resolution) is

TABLE 192B.4 Recommendations for *Pneumocystis* Pneumonia Prophylaxis and CD4⁺ Monitoring for Infants and Children Exposed to or Infected With HIV

Age, HIV Infection Status	Prophylaxis	CD4 ⁺ Monitoring
Birth to 4–6 wk, HIV exposed	No prophylaxis	—
4–6 wk to 12 mo, HIV exposed	No prophylaxis ^a	—
<12 mo, HIV infected or indeterminate	Prophylaxis	Every 3–4 mo
1–5 y, HIV infected	Prophylaxis if CD4 ⁺ count is <500 cells/μL or CD4 ⁺ percentage is <15%	Every 3–4 mo
6–12 y, HIV infected	Prophylaxis if CD4 ⁺ count is <200 cells/μL or CD4 ⁺ percentage is <15%	Every 3–4 mo

^aUntil HIV infection is presumptively excluded (i.e., documentation of two negative virologic test results, one at age ≥2 wk and one at age ≥4 wk) or definitively excluded (i.e., documentation of two negative virologic test results, one at age ≥1 mo and one at age ≥4 mo). For these definitions of HIV exclusion to be valid, the infant must not be breastfeeding.

Modified from Mofenson LM, Brady MT, Danner SP, et al. Guidelines for the prevention and treatment of opportunistic infections among HIV-exposed and HIV-infected children: recommendations from CDC, the National Institutes of Health, the HIV Medicine Association of the Infectious Diseases Society of America, the Pediatric Infectious Diseases Society, and the American Academy of Pediatrics. *MMWR Recomm Rep*. 2009;58(RR-11):1–166.

recommended (Table 192B.4). Proposed pediatric regimens include TMP-SMX at 150 mg/m² per day and 750 mg/m² per day, respectively, given in two divided doses on 3 consecutive days/week (alternative regimens include a single dose on 3 consecutive days/week, two divided doses on 3 alternate days/week, and two divided doses daily); dapsone for children 1 month of age or older at 2 mg/kg daily (single dosing not to exceed 100 mg/day) or 4 mg/kg weekly (single dosing not to exceed 200 mg); pentamidine (aerosolized [300 mg by Respigard II inhaler monthly]) for children 5 years or older; and atovaquone (30 mg/kg daily for children 1–3 months and >24 months and 45 mg/kg daily for children 4–24 months).¹⁸⁷

For adults and adolescents, recommendations to discontinue secondary PJP prophylaxis can be considered when there is documentation of immune restoration (i.e., CD4⁺ T-cell counts that have increased to >200 cells/mm³ for ≥3 months as a result of HAART).⁴² Data from the European PJP-Withdrawal Study Group suggest that with immunorestitution by HAART, the risk for PJP development is low and that withdrawal of PJP prophylaxis as recommended if the adult host appears to be a reasonable risk.²⁷⁴ US guidelines continue to recommend lifelong primary PJP prophylaxis for individuals who acquired PJP before reaching 13 years of age.¹⁸⁸

Primary PJP prophylaxis (i.e., therapy initiated to prevent primary infection) for adults and children is accepted as standard care.⁴² Pediatric regimens and dosing for secondary PJP prophylaxis are not different from those outlined earlier. In 1993, the CDC published the first PJP prophylaxis guidelines for HIV-infected children. The guidelines linked the institution of therapy to the level of immunosuppression as measured by the CD4⁺ cell count or percentage.³⁸ Guidelines for PJP prophylaxis were modified in 2009.¹⁸⁷ The most significant change in the revised guidelines concerned diagnosing HIV infection and presumptively excluding HIV infection in infants, which affected the need for initiation of prophylaxis to prevent PJP in neonates.

Based on the revision, prophylaxis is not recommended for infants who meet criteria for being definitively or presumptively not HIV infected. For nonbreastfeeding infants with no positive HIV virologic test results, presumptive exclusion of HIV infection can be based on

two negative virologic test results (i.e., one obtained at age ≥2 weeks and one obtained at 4 weeks of age), on one negative virologic test result obtained at 8 weeks of age or older, or on one negative HIV-antibody test result obtained at 6 months of age or older. Definitive exclusion of HIV infection is based on two negative virologic test results (one obtained at age ≥1 month and one obtained at age ≥4 months) or on two negative HIV-antibody test results from separate specimens obtained at 6 months of age or older. For presumptive and definitive exclusion of infection, the child should have no other laboratory or clinical evidence of HIV infection.

Infants born to HIV-infected mothers should be considered for prophylaxis beginning at 4 to 6 weeks of age. HIV-infected infants should be administered prophylaxis until 1 year of age, at which time they should be reassessed on the basis of the age-specific CD4⁺ T-cell count or percentage thresholds. Infants with indeterminate HIV infection status should receive prophylaxis until they are determined to be HIV uninfected or presumptively uninfected with HIV. Data from the Pediatric AIDS Clinical Trials Group protocol 1088 documented that primary PJP prophylaxis for HIV-infected children could be discontinued safely with immune restoration on stable antiretroviral therapy.¹⁹⁸

Infection with *Mycobacterium avium* Complex

The incidence of *Mycobacterium avium* complex (MAC, formerly *Mycobacterium avium-intracellulare*), which caused disseminated infections in HIV-infected adults and children in the early 1980s and 1990s, waned significantly with the increasing and successful use of HAART. In a 1990 review of opportunistic infections in pediatric patients with AIDS, 43 (7.8%) of 552 children from birth to 9 years of age were found to have disseminated MAC infection.¹¹⁷ The incidence of pediatric MAC infection among HIV-infected children dropped from 1.3 cases per 100 patient-years reported before 1997 to 0.2 cases per 100 patient-years after 1997.¹⁹⁹ Epidemiologically, MAC has been linked to significant immunosuppression (i.e., CD4⁺ T-cell counts <50 cells/mm³) in adults.^{42,189} Researchers observed that the development of MAC infection in children can be associated with CD4⁺ T-cell counts greater than 50 cells/mm³, especially in children younger than 6 years.²³⁵

Symptoms of MAC infection include fever, malaise, weight loss, anorexia, and night sweats. Gastrointestinal manifestations have included abdominal pain, diarrhea, malabsorption, and intestinal perforation. Rarely, MAC has been reported with extrabiliary obstructive jaundice (presumably due to lymphadenopathy) and endobronchial masses. The diagnosis of disseminated MAC infection relies on identification of the microorganisms from the blood, lymph tissue, bone marrow, liver, lungs, and gastrointestinal tract.

Therapy for disseminated MAC infection in the pediatric population includes some combination of clarithromycin or azithromycin (maximal dosing of 500 mg and 250 mg, respectively) or rifabutin (maximal dosing of 300 mg), or both regimens. The epidemiologic link with severe immunosuppression and the advent of therapeutic prophylactic interventions (i.e., clarithromycin or azithromycin and/or rifabutin) prompted the implementation of MAC prophylaxis guidelines for adults, adolescents, and older children (≥6 years) with CD4⁺ T-cell counts lower than 50 cells/mm³.³⁹ Primary MAC prophylaxis can be discontinued in HIV-infected children older than 2 years of age receiving stable HAART for 6 months or more and sustaining (>3 months) CD4⁺ T-cell recovery.¹⁹⁸

An unusual immune reconstitution inflammatory syndrome (IRIS) has been described as a paradoxical event after immune recovery has been achieved in adults and adolescents receiving HAART.²⁵⁸ IRIS is associated with reactivation of opportunistic infections such as MAC. Activation of other latent complications, including carcinoma and neurologic symptoms, has been described.²⁶⁷ Data indicated that MAC prophylaxis with azithromycin did not prevent IRIS.²¹⁷ In children with IRIS, treatment of the reactivated opportunistic infection can include administration of antiinflammatory agents, including systemic corticosteroids.

Tuberculosis

Overall case rates of tuberculosis in the United States are declining, with 4.4 new cases per 100,000 people (total of 13,299 cases) reported

in 2007. The percentage of patients with tuberculosis and known HIV infection also decreased from 15.0% in 2003 to 12.4% in 2006.³⁶ Primary disease accounts for one third or more of cases of tuberculosis in HIV-infected populations.²⁸⁶ In a cohort of pregnant and nonpregnant HIV-infected women monitored in a multicenter longitudinal study, the prevalence of tuberculosis determined by medical history or positive skin tests was 14%.¹⁸⁸

Children most commonly are infected with *Mycobacterium tuberculosis* from exposure in their immediate environment, usually the household. In a study of 60 HIV-infected families, the incidence of tuberculosis was approximately 6%, with HIV-infected and HIV-uninfected children affected. The vector for transmission was identified as an infected family member or caregiver.¹¹ Tuberculosis should be considered in the differential diagnosis of pulmonary disease in HIV-exposed children.

The principles for treating tuberculosis in the HIV-infected child are the same as for the HIV-uninfected child and should include at least a four-drug regimen. However, treating tuberculosis in an HIV-infected child is complicated by antiretroviral drug interactions with the rifamycins and overlapping toxicities caused by antiretroviral agents and tuberculosis medications. The duration of treatment is 9 to 12 months, with the longest duration for children with extrapulmonary disease.³⁴ Secondary prophylaxis is not recommended for children who have had a prior episode of tuberculosis.

Cytomegalovirus

In the pre-antiretroviral era, CMV caused 8% to 10% of pediatric AIDS-defining illness.¹³⁸ The adult spectrum of CMV disease, including retinitis, pneumonitis, esophagitis, gastritis, colitis, hepatitis, cholangitis, and encephalitis, is not reported uniformly in the pediatric AIDS literature. CMV can cause primary pneumonitis in children and can be associated with other pulmonary pathogens, especially *Pneumocystis*. Unusual gastrointestinal manifestations have included pyloric obstruction, enterocolitis, and oral and esophageal ulcers. CMV retinitis is the most frequent severe manifestation of CMV disease among HIV-infected children, accounting for approximately 25% of CMV AIDS-defining illnesses.⁵¹ However, it appears to be decreasing in incidence with the wider use of HAART.¹⁹⁹ Annual CMV antibody testing is recommended beginning at 1 year of age for CMV-seronegative, HIV-infected infants and children who are severely immunosuppressed.

Treatment of CMV disease associated with HIV infection focuses on slowing progression of disease and not on a curative outcome. Therapeutic intervention includes the use of ganciclovir, valganciclovir, foscarnet, or cidofovir. These drugs have significant side effects, including bone marrow suppression and renal toxicity. Administration of these agents is divided into induction and maintenance dosing. The optimal interval for efficacy has not been determined and often is selected on an individual basis. Although many adults report experiencing subjective and objective improvement while receiving therapy, discontinuation of therapy is associated with high relapse rates, independent of the affected site.

Careful monitoring of children receiving treatment for CMV and antiretroviral therapy is imperative because the use of both classes of agents can depress bone marrow function. CMV end-organ disease is best prevented by antiretroviral therapy to maintain CD4⁺ T-cell count greater than 100 cells/mm³. If this is not possible, prophylaxis with valganciclovir can be considered for HIV-infected older children who are CMV seropositive and have severe immune suppression (i.e., CD4⁺ T-cell count <50 cells/mm³) at a dose of 15 mg/kg per dose every 12 hours and using a 50-mg/mL pediatric solution or using tablets if the child weighs enough to receive adult doses of valganciclovir.

Prevention of complications of CMV in HIV-infected children with severe immunosuppression includes careful and regular (i.e., every 4–6 months) retinal monitoring for evidence of eye disease. After secondary prophylaxis for disseminated CMV disease is initiated, its discontinuation should be considered on a case-by-case basis because current data to support discontinuation are limited.²⁸¹ As reported with MAC, reactivation of CMV disease in IRIS has been described.

Other Herpesvirus Infections

Infections with the herpesvirus family occur in HIV-infected children. In a US study during the HAART era, the incidence of systemic HSV

infection was 0.9 case per 100 child-years. Infection was most common among children with a reduced CD4⁺ T-cell percentage (<25%).¹⁰² HSV infection in pediatric AIDS typically has been limited to mild to severe localized infections without reports of dissemination. Varicella-zoster virus (VZV) and herpes zoster virus (HZV) infections have contributed significant morbidity to HIV-infected people. Disseminated and chronic HZV infections are reported for pediatric patients with AIDS.

Because episodes of HSV disease can be treated successfully, chronic therapy with acyclovir is not required after lesions resolve. However, children who have frequent or severe recurrences can be administered daily suppressive therapy with oral acyclovir.⁸² Prevention of herpes infections in school-aged children is especially important because exposure to varicella may be considerable. Administering varicella-zoster immune globulin (VariZIG) should be considered for susceptible HIV-infected children with exposure to VZV. Because the varicella vaccine is an attenuated live viral vaccine, its use in HIV-infected children is limited to children with asymptomatic or mildly symptomatic HIV disease and no evidence of immune suppression.⁴³

Fungal Diseases

The most common fungal infections among HIV-infected children are caused by *Candida* spp. Oral thrush and diaper dermatitis occur among 50% to 85% of HIV-infected children.¹⁰² Affected mucous membranes or skin often does not respond well to treatment with topical antifungal agents. Systemic therapy with one of the oral azoles, including fluconazole, ketoconazole, or itraconazole, is effective in oropharyngeal or esophageal candidiasis. In severe fungal infections, amphotericin B or other agents effective against the *Candida* spp. should be administered intravenously. Because of limited experience with children and no information about HIV-infected children, data are insufficient to recommend echinocandin class antifungal medications, including caspofungin, micafungin, and anidulafungin, as first-line agents for invasive candidiasis in children.²⁴⁷ Prophylaxis for candidal infections is not recommended because of concern about development of resistance to azoles such as fluconazole, which could limit the use of these agents in the care of disseminated or mucosal disease.⁴²

Other disseminated fungal diseases, such as histoplasmosis and cryptococcosis, less commonly affect pediatric patients with AIDS. Histoplasmosis may be prevalent among HIV-infected children who reside in parts of the United States where *Histoplasma capsulatum* is endemic. Symptoms of histoplasmosis include fever, rash, cough, lymphadenopathy, splenomegaly, thrombocytopenia, low-grade disseminated intravascular coagulopathy, acute respiratory distress syndrome, meningoencephalitis, and neurologic abnormalities consistent with intracranial mass lesions. Symptoms of cryptococcosis include fever, headache, pulmonary involvement, and subacute meningitis or meningoencephalitis.¹⁸⁵

Because of the low incidence of histoplasmosis among pediatric HIV-infected patients, possibility of drug interactions, potential antifungal drug resistance, and cost, the routine use of antifungal medications for primary prophylaxis of *Histoplasma* infections in children is not recommended. However, primary prophylaxis for adults and adolescents is suggested for those with compromised immune systems. Fluconazole is suggested as primary cryptococcosis prophylaxis for adults and adolescents with CD4⁺ T-cell counts of less than 50 cells/mm³, and itraconazole is advised for histoplasmosis prophylaxis in adults and adolescents with CD4⁺ T-cell counts of less than 150 cells/mm³.

The safety of discontinuing secondary prophylaxis for cryptococcosis after immune reconstitution with HAART has not been studied in children, and decisions in this regard should be made on a case-by-case basis. Recommendations to discontinue prophylaxis as a result of HAART-related improved immune function have been developed for cryptococcosis and include sustained (>6 months) CD4⁺ T-cell counts higher than 200 cells/mm³.¹³⁷ No such recommendations exist for discontinuation of histoplasmosis prophylaxis in HIV-infected adults or adolescents with evidence of HAART-related reconstitution of immunity.

Bacterial Diseases

Pediatric patients have an increased incidence of severe bacterial infections, including infections with *Streptococcus pneumoniae*, *Staphylococcus*

aureus, and various gram-negative organisms. One of the most common first-time infections in HIV-infected children is a bacterial infection (e.g., bacterial pneumonia).¹⁰² In a study of 372 HIV-infected children monitored for a median of 17 months, 14% experienced one or more laboratory-proven serious bacterial infections. Later findings suggested that the rates of bacterial disease dropped from 4.7 cases per 100 patient-years before 1997 to 0.2 cases per 100 patient-years after 1997 (i.e., HAART era).¹⁹⁹

Reported clinical infections included bacteremia, pneumonia, osteomyelitis, meningitis, and sinusitis. Therapy is directed against the specific isolated bacterial pathogen, and the dosing and duration of therapy depend on the affected site. Prophylaxis against bacterial infections initially should include vaccination with appropriate childhood vaccines, including *Haemophilus influenzae* type b (Hib) vaccine, pneumococcal conjugate vaccines, meningococcal conjugate vaccines, and influenza vaccine.²⁰⁶ Other medications available for bacterial prophylaxis include intravenous immune globulin (IVIG), TMP-SMX, atovaquone, and azithromycin. IGIV is no longer recommended for primary prevention of serious bacterial infections in HIV-infected children unless hypogammaglobulinemia exists or functional antibody deficiency is demonstrated.

COMPLICATIONS

Pulmonary Complications

In addition to PJP and chronic sinopulmonary infection, noninfectious pulmonary complications of pediatric AIDS cause morbidity. Chronic lung disease is common in HIV-infected children with increasing age.²⁵² A longitudinal birth cohort study reported a cumulative incidence of chronic radiographic lung changes in HIV-infected children of 33% by 4 years of age.²⁰⁵ The spectrum of chronic HIV-associated lung disease includes lymphocytic interstitial pneumonia (LIP) or pulmonary lymphoid hyperplasia (PLH), chronic infections, IRIS, bronchiectasis, and malignancies.²⁹³ Lymphoid interstitial pneumonitis and *P. jiroveci* pneumonitis have largely disappeared in developed countries but remain a significant problem in developing countries.²⁹³ The incidence of *P. jiroveci* pneumonitis (previously 1.3 per 100 child-years) is now 0.13 per 100 child-years. LIP is similarly affected by HAART. The rate of bacterial pneumonia remains relatively high (2.2 per 100 child-years),

although it is markedly reduced from the period before HAART, when the incidence was fivefold higher.²⁹³ Bronchiectasis may reappear as a serious complication of HIV infection if chronic inflammation of the lung (usually controlled by HAART) takes its toll over the years; the oldest surviving HIV-infected children are now approaching 30 years of age.

Histopathologically, LIP and PLH appear to be distinct entities, although whether these disorders represent a continuum of reactive hyperplasia of lymphoid tissue is somewhat controversial. In LIP, small lymphoid infiltrates are dispersed throughout parenchymal lung tissue and often are accompanied by alveolar epithelial hyperplasia and interstitial widening. PLH describes larger, dense nodular aggregates of lymphoid tissue in distal parenchymal tissue and the walls of bronchi and bronchioles (Fig. 192B.3B). Compression of blood and lymphatic vessels by these nodules may contribute to the accompanying clinical interstitial widening. The cause of LIP/PLH has not been defined. Simultaneous infection with EBV and HIV may amplify the risk of LIP. B lymphocytes infected with EBV are very susceptible to HIV infection in vitro and can enhance intrapulmonary replication of HIV.²⁶⁴

Clinically, LIP/PLH is characterized by a nonproductive cough and the insidious onset of progressive hypoxia. The hypoxemia may be subtle and best appreciated during febrile, upper respiratory tract illnesses. Digital clubbing, generalized lymphadenopathy, chronic parotitis, or failure to thrive may accompany LIP/PLH.^{216,260} Radiographically, LIP/PLH often demonstrates characteristic interstitial infiltrates with a nodular pattern (see Fig. 192B.3A). This radiographic picture frequently mimics that of miliary tuberculosis and warrants exclusion of this pulmonary infection.

In an immunocompromised, anergic, HIV-positive child, simple delayed hypersensitivity skin testing for exclusion of tuberculosis may not suffice, and BAL or gastric aspiration for detection of acid-fast microorganisms may be necessary. Lung biopsy is the definitive diagnostic procedure for LIP/PLH. However, in HIV-infected children, a presumed diagnosis of LIP/PLH by the less invasive exclusion of infectious pathogens is preferred.

Therapy for LIP/PLH is not defined clearly because the clinical outcome varies. HIV-infected children with LIP/PLH have had spontaneous remissions without therapeutic intervention, whereas other affected children progress to respiratory insufficiency and failure. Therapeutic

FIG. 192B.3 (A) Chest radiograph documents parenchymal nodularity in a 3-year-old child with perinatal AIDS. (B) Pulmonary lymphoid hyperplasia in the child produced histologic changes, including interstitial widening and prominent peribronchial lung nodes.

interventions have included IVIG supplementation, antiretroviral therapy, corticosteroids (i.e., daily or alternate-day dosing of 0.5–2.0 mg/kg per day), and observation. No significant associated infectious sequelae (e.g., bacteremia, fungemia) of corticosteroid use were reported for treated children. Supportive therapy consisting of oxygen supplementation, chest physical therapy, and adequate nutritional intake is helpful.^{106,216}

Other noninfectious pulmonary complications have been reported less frequently for the pediatric HIV-infected population. Evidence of an increased incidence of asthma among HIV-infected children, adolescents, and young adults was shown in a series of peer-reviewed publications.^{88–90,116,254} In the most recent of these, physician-diagnosed asthma and asthma medication use associated with at least a 30% increase in the asthma incidence (i.e., HIV-infected vs. HIV-exposed but not infected patients) and offered compelling evidence that patients had more than one manifestation of allergic disease.²⁵⁴ The rate of atopic dermatitis also increased among HIV-infected patients. It appeared shortly after birth and before the asthmatic child was diagnosed, resembling the order that it appears in the general pediatric population.

Two mechanisms that may underlie the increased incidence of asthma among HIV-infected youth have been discovered. The first is genetic inheritance of HLA class I genes that are associated with new disease appearance after patients with HIV infection have had immune reconstitution with HAART.⁸⁸ The second mechanism that may be applicable to the appearance of new disease in immunoreconstituted patients infected with HIV is a sudden return of cellular immunity (i.e., measured by CD4⁺ T-cell increases), which may precipitate a dysregulated attack on HIV in the airways, and commensal fungi that colonize or infect the airways of HIV-infected patients.¹⁶ In experimental animal models, the sudden burst of immune stimulation precipitates an asthma attack.^{222,223}

Studies of asthma and HIV infection have been extended in the Pediatric HIV/AIDS Cohort Study of a cohort of older children, adolescents, and young adults who were HIV infected ($n = 218$) and HIV exposed but uninfected ($n = 152$).²⁵² The stimulus for this ongoing research was the National Heart, Lung, and Blood Institute supplemental grant that enabled the performance of pulmonary function tests (PFTs) to augment the clinical information on asthma, asthma medications, and physician examination with objective evidence of abnormal pulmonary airflow recorded by a spirometer. A key outcome of PFTs is the rate (i.e., number of abnormal/total number of patients) with obstructive airflow (i.e., difficulty breathing). For the HIV-infected and HIV-exposed but uninfected cohort, the rate of patients with obstructive airflow is elevated at 17% to 20% (vs. 8.6% for US youth), but the rate of reversal of obstructive airflow after inhalation of a bronchodilator (i.e., criteria for asthma) was less for the HIV-infected group compared with the HIV-exposed but uninfected group of youth.

When only the obstructive subgroup was identified by PFTs, the rate of reversal of obstructive airflow for the HIV-infected group was only 50%, compared with 75% for the HIV-exposed but uninfected subgroup. The lack of reversibility of airflow obstruction in patients with asthma can be attributed to a complex mixture of asthma and chronic obstructive pulmonary disease (COPD), known as the asthma-COPD overlap syndrome. Immune dysregulation has been implicated in these disorders. Investigators looked for evidence of objective involvement of the immune system and showed reversibility by using time-honored methods: control of total nonspecific serum IgE levels by the CD4⁺ T cells and ability of both subgroups to produce specific IgE in response to common inhaled allergens, such as dust mites.

These approaches revealed that the HIV-infected subgroup showed no immune control of total serum IgE levels and had less specific IgE levels in response to common allergens than the noninfected subgroup. The tests indicated the presence of an additional pulmonary complication of HIV infection, one that coexisted with asthma in a complex illness that will most likely demonstrate considerable pulmonary comorbidity as patients grow older. The overall findings strongly indicate that perinatally HIV-infected youth need to be followed for an extended period in case they develop serious obstructive pulmonary complications of HIV infection and that additional control subgroups are essential for the demonstration of the specific destructive nature of the asthma-COPD overlap syndrome (e.g., HIV-unexposed, uninfected subjects).

Central Nervous System, Neurobehavioral, and Neurocognitive Complications of Pediatric HIV/AIDS

Neurologic abnormalities have been documented in people with HIV and can be attributed to opportunistic infections, adverse events of primary treatment, or primary infection with HIV, especially in light of HIV's described tropism for monocytes. Diverse neurologic and neurobehavioral deficits that occur in children with HIV-1 infection include abnormal neurologic examination findings (e.g., global pyramidal tract signs, hemiparesis, peripheral neuropathy, visual, hearing impairment), neurobehavioral problems, encephalopathy, and epilepsy.^{13,105,131} Children with severe immunosuppression, those with immune activation not receiving antiretroviral therapy, and those who are growth impaired and younger than 1 year of age are at greatest risk for neurologic complications.^{145,180} Antiretroviral treatment is associated with fewer severe CNS effects of HIV infection, such as encephalopathy. However, increases have been found in mental health and neurodevelopmental conditions. A study of two cohorts, P219C (2004–07) compared with P1074 (2008–14), showed the largest increases in substance or alcohol abuse, anxiety disorders, trauma- or stress-related disorders, impulse control and mood disorders, and learning and communication disorders.¹⁸⁴

An encouraging study of early viral suppression improving neurocognitive function of HIV-infected children was made by Crowell and colleagues.⁶⁴ Measurements for almost 400 HIV-infected children from two US-based multisite studies in which IQ scores, perceptual receptive reasoning, and verbal comprehension were compared for HIV-infected patients with or without viral suppression. HIV-infected children with viral suppression scored significantly higher in several neurocognitive assessments than HIV-infected children not viral suppressed.

In 1994, HIV encephalopathy in children was adapted as a criterion for the diagnosis of AIDS. It consists of at least one of the following features persisting for at least 2 months: failure to attain or loss of developmental milestones or loss of intellectual ability, verified by a standard developmental scale or neuropsychological tests; impaired brain growth or acquired microcephaly demonstrated by head circumference measurements or brain atrophy identified by computed tomography (CT) or magnetic resonance imaging (MRI) (i.e., serial imaging is required for children <2 years); and acquired symmetric motor deficit manifested by two or more of the following: paresis, pathologic reflexes, ataxia, or gait disturbance.⁴⁰

The precise pathogenesis of the encephalopathic changes associated with HIV infection remains elusive, although cellular tropism of HIV has been implicated.¹⁴¹ Most children with involvement of the CNS show significant brain atrophy histopathologically. Inflammatory lesions usually are sparse and alone cannot account for the significant amount of atrophy observed. Other factors potentially contributing to diminished brain size have included the following: direct or indirect interference of HIV with brain growth (i.e. HIV toxic effect vs. competition with brain growth factors such as neuroleukin), severe malnutrition, severe hypoxia from cardiac and pulmonary compromise, and therapeutic regimens for infectious or noninfectious processes that mandate the prolonged use of medications that can inhibit brain growth.^{157,242}

Using sophisticated radiologic scanning technology, Uban and coworkers²⁶⁸ demonstrated alteration of the microstructure of the cerebral white matter cells in perinatally HIV-infected older children, adolescents, and young adults.²⁶⁸ Patients with more severe HIV disease exhibited reduced fractional signaling of the right inferior frontal-occipital and left uncinate tracts, elevated diffusion in the F minor tract, and increased white matter streamlines in the left inferior bundle. Increased peak viral load of patients was associated with decreased working memory performance and was partly mediated by reductions in the right inferior frontal occipital fractional signaling node. Conclusions of this pediatric study imply that HIV-infected youth have a higher risk of changes in white matter microstructure than youth controls and that certain alterations are related to previous disease severity. White matter alterations possibly mediate associations between HIV disease severity and working memory.

A prospective study of a cohort of 319 perinatally HIV-infected children 6 to 17 years of age observed over a 2-year period indicated

associations of past and current CDC class C designation with less severe attention-deficit/hyperactivity disorder (ADHD) inattention symptoms, older age at nadir CD4⁺ T-cell percentage and lower CD4⁺ T-cell percentage at study entry with more severe conduct disorder symptoms, higher RNA viral load at study entry with more severe depression symptoms, and lower CD4⁺ T-cell percentage at study entry with less severe symptoms of depression. There was little evidence of an association between specific antiretroviral therapy and severity of psychiatric symptoms. A lower nadir CD4⁺ T-cell percentage was associated with worse quality of life, worse Wechsler Intelligence Scale for Children Coding Recall scores, and worse social functioning.¹⁹⁷ In a cohort of perinatally HIV-infected children with severe disease, Kapetanovic and colleagues concluded that higher CD4⁺CD38⁺HLADR⁺ percentage was associated with a neuroprotective effect and higher percentage of CD4⁺CD38⁺ but that HLADR⁺ T cells may be deleterious.¹³² ADHD, learning disability, and graphomotor weakness have been described in higher proportions among HIV-infected children with transfusion-acquired infection.

Behavioral, neurodevelopmental, and occasionally, imaging improvements have been documented with antiretroviral therapy. In a study of 146 perinatally HIV-infected children born between 1990 and 2003, the prevalence of encephalopathy (i.e., progressive or static) decreased from 40.7% before 1996 (i.e., limited combination antiviral therapy) to 18.2% after that year.²⁴⁹ In this cohort, neurocognitive scores remained stable over the course of a 6-month period for children receiving combined antiviral therapy, and only a weak association with lowered viral load could be found. Antiviral therapy must achieve effective serum and plasma concentrations and must be able to cross the blood-brain barrier and affect HIV-infected CNS monocytes. On the contrary, a longitudinal cohort study involving HIV-infected and HIV-exposed but uninfected infants and children reported the effects of PI-based HAART and showed a positive but limited impact on neurodevelopmental trajectories and the rate of significant cognitive and motor impairment in HIV-infected infants and young children during the first 3 years of life.¹⁵⁵ In this study, infants with immune suppression (i.e., CD4⁺ T-cell levels <25%) seemed to be most vulnerable with respect to neurodevelopmental functioning, demonstrating mental and motor scores lower than those of the HIV-negative infants and HIV-infected infants with less immune suppression.

Sleep disturbances, neurocognitive deficits, and abnormal psychosocial function are associated with abnormal cytokine levels in children with HIV infection.^{18,207,241,285} A National Heart, Lung, and Blood Institute (NHLBI)-funded study attempted to discern a molecular pathway of these complications of pediatric HIV infection by assessing proinflammatory cytokine production in CD4⁺ and CD8⁺ T cells, disturbed sleep patterns, and results of neurodevelopmental testing in HIV-infected versus HIV-exposed children.⁸⁷ Compared with HIV-exposed children, there were significant associations for HIV-infected children for changes in intracellular proinflammatory cytokines (i.e., tumor necrosis factor- α , IFN- γ , IL-12), sleep patterns (particularly increased daytime sleep), and lower neurocognitive scores on socioemotional, behavioral, and executive function: working memory and mental fatigue; verbal memory; and sustained concentrations and vigilance. The authors of this sleep study of HIV-infected children proposed that therapies that reduced immune-mediated inflammation and prescribed sleeping habits could improve the neurocognitive and psychosocial problems.⁸⁷

Gastrointestinal Complications

Gastrointestinal complications of HIV disease are encountered frequently in children and adults. In untreated children, malnutrition is one of the most frequent and devastating complications of pediatric HIV, and it predicts morbidity and mortality. Malnutrition in HIV-infected children has several causes, including reduced oral intake (i.e., HIV-induced primary cachexia, opportunistic infections of the upper gastrointestinal tract, and medication side effects), malabsorption (i.e., HIV alone or infections of the gastrointestinal tract), altered metabolic states (i.e., proinflammatory effects of chronic HIV infection), and socioeconomic factors.¹³⁵

Although the prevalence of AIDS-associated wasting has declined in the developed world because of HAART, it is still a concern for children in rich and poor nations. HIV and its complications also have

been associated with specific nutritional disorders. Higher HIV viral load, lower CD4⁺ T-lymphocyte counts, infections, maternal drug use, and some antiretrovirals such as zidovudine and lopinavir plus ritonavir, have been associated with growth problems.^{153,182} Wasting and weight loss in HIV-infected individuals appear to be independent predictors of death and are associated with lower CD4⁺ T-cell counts.^{86,168}

The intestine is a primary target organ for HIV and is important in the pathogenesis of HIV infection. Among untreated HIV-infected children, as many as 80% will have one or more intestinal abnormalities at a given time. The pattern of intestinal dysfunction may change with time and can occur without evident cause or change in clinical HIV stage or immunologic status.^{66,114} The transactivator of transcription (Tat), a regulatory protein that drastically enhances the efficiency of HIV DNA transcription, may be involved in intestinal dysfunction (i.e., HIV enteropathy) because it can impair enterocyte proliferation by targeting its L-type calcium sodium-glucose symporter. This pathway may explain many features of intestinal dysfunction, such as intestinal atrophy, carbohydrate malabsorption, and diarrhea, that are frequently observed.⁶⁶ Associated protein and micronutrient (e.g., zinc, selenium) deficiencies have been documented in HIV-infected adults and children.⁵⁰ Despite use of HAART, gastrointestinal conditions, nutritional deficiencies, and fluid and electrolyte disorders continue to be the most frequently described diagnoses for hospitalized HIV-infected children.¹⁴⁴

Specialized nutritional supplements such as nucleotides, polyamines, probiotics, and zinc can improve gastrointestinal absorption. Zinc may control diarrhea in HIV-infected children because it specifically counteracts Tat-induced intestinal ion secretion.³¹ Polyamines such as spermine, spermidine, and putrescine can modulate intestinal maturation. Probiotics, including *Saccharomyces boulardii*, target the gastrointestinal tract and have antioxidant, antibacterial, enzymatic, antiinfective, metabolic, and antiinflammatory activity. However, their effectiveness in HIV care is not well established.^{73,97}

The use of more potent antiretroviral therapy regimens, particularly those including PIs, has resulted in unwanted biochemical lipid abnormalities and changes in body composition for some HIV-infected adults and children. In a 2004 study of 94 infected children receiving long-term PI-containing antiviral regimens, 10% developed redistribution of fat, 52% developed dyslipidemia without associated somatic changes, and 38% had no associated findings.²⁶¹ In this cohort, changes in redistribution of fat and dyslipidemia were most likely to occur near ages consistent with the start of puberty (age 10–15 years).

In a multicenter US Perinatal AIDS Collaboration Transmission Study, 178 HIV-infected children were evaluated for hypercholesterolemia or hypertriglyceridemia, and 47% and 67%, respectively, met criteria for these diagnoses at least once during their follow-up.³³ In this cohort, hypercholesterolemia was associated with multiple PI-containing regimens and an undetectable HIV viral load as measured by RNA PCR. Hypertriglyceridemia was predicted by elevated body mass index and use of the PI ritonavir (RTV). These clinical findings of lipodystrophy and dyslipidemia have been treated with some success with diet, exercise, or lipid-lowering medications, although the lipid-lowering medications may result in drug-drug interactions when they are combined with antiviral agents. Antiretrovirals regimens with integrase inhibitors are less associated with lipodystrophy and dyslipidemia.

Nutritional goals for HIV-infected children should include preservation of normal growth and development, provision of adequate amounts of all nutrients, and prevention of malabsorption and deficiencies of nutrients that alter immunologic function while improving quality of life.¹⁸¹

Malignancy

HIV infection has been associated with an increased risk of AIDS-defining and non-AIDS-defining malignancies.⁸⁰ Initiation of HAART in the mid-1990s has resulted in a significant decrease in AIDS-defining neoplasms such as Kaposi sarcoma and certain lymphomas, particularly primary CNS lymphoma and high-grade B-cell non-Hodgkin lymphoma, but malignancies continue to be reported.^{57,80,109,130} Most malignancies that affect HIV-infected children are non-Hodgkin lymphomas, although the leading cause of malignancy in youth in Africa is Kaposi sarcoma.^{81,109,136,140}

In a retrospective study of 4954 children with AIDS in the United States (1978–96), approximately 2.5% had documented malignant diseases: non-Hodgkin lymphoma ($n = 100$), Kaposi sarcoma ($n = 8$), leiomyosarcoma ($n = 4$), and Hodgkin disease ($n = 2$); 10 others had unspecified cancers.¹⁵ Associated in situ infection with HIV or EBV, or both, has been documented in pediatric malignancies, although the precise role in pathogenesis is not defined. In a case-control study, a high viral burden of EBV was associated with the development of malignancy, but only in children with CD4⁺ T-cell counts greater than 200/ μ L.²¹⁹ Early chemotherapeutic intervention has enhanced quality of life and longevity and often has been provided in conjunction with antiretroviral therapy.

The pathogenesis of HIV-related and non-HIV related Kaposi sarcoma has been elucidated, and human herpesvirus 8 has been documented in lesions.^{121,150} Pathogenesis has been linked to oncogenesis and cytokine-induced growth. The clinical manifestations of Kaposi sarcoma associated with AIDS affect many organs. The skin, gastrointestinal tract, lungs, and heart are affected by Kaposi sarcoma.⁸ Management of Kaposi sarcoma has improved with increasing use of HAART to restore immune function in HIV-infected individuals.^{81,215}

Leiomyomas and leiomyosarcomas are among the common malignancies observed in HIV-infected children. Although these cancers are usually seen in the gastrointestinal tract, the lungs or spleen can also be involved. The pulmonary lesions are usually visible as nodules on chest CT, whereas the gastrointestinal tumors manifest as obstruction, abdominal pain, and bloody diarrhea.¹⁰⁹

Since the advent of HAART, HIV-related malignant disease in the United States is reported less frequently. In a study of 2969 HIV-infected children observed in the Pediatric AIDS Clinical Trials Group 219/219C from 1993 to 2003, only 37 cases of malignant disease were reported, representing a prevalence of 0.6% malignancies and an incidence of 1.56 cases per 1000 person-years.¹³⁶ In this analysis, the standardized incidence cancer rate for infected children was 10.08 compared with uninfected but exposed controls. The incidence of cancer was highest among children with severe immunocompromise and those who had received HAART for less than 2 years.

Other Complications

Cardiac Abnormalities

The most direct way to study pediatric cardiovascular disease in HIV infection is to study adults with HIV-related cardiovascular disease. Adults with HIV infection are 50% to 100% more likely to have cardiovascular disease.²⁶⁶ Studies at the Veterans Affairs Agency have found a less than 50% incidence of myocardial infarction among non-HIV-infected people compared with HIV-infected individuals.

Coronary artery plaque is the leading factor in the cause of myocardial infarction.⁹² Scanning techniques have demonstrated that plaque is the culprit in the ensuing myocardial infarction.¹⁵⁸ Adherence to antiretroviral therapy by adults has produced a significant reduction in cardiovascular events.¹⁸⁶

Cardiac manifestations of HIV infection in children include left ventricular dysfunction, increased left ventricular mass, myocarditis, and pericardial effusion.²⁷⁷ HIV-infected children have been described with congestive heart failure and cardiomegaly, cardiac tamponade, nonbacterial thrombotic endocarditis, conduction disturbances, and sudden death, presumably due to primary ventricular arrhythmia associated with severe cardiomyopathy. In a postmortem analysis of 30 HIV-infected children followed longitudinally in the prospective P2C2 HIV Multicenter Study, 50% had cardiomegaly with associated clinical findings of increased heart rate, increased left ventricular mass, and chronic heart disease.¹³³

Asymptomatic children with HIV infection can exhibit cardiac abnormalities. In a cross-sectional study of 49 HIV-infected children, carotid artery wall stiffness was larger and systolic-diastolic variations in diameter of the carotid artery were significantly lower compared with controls in the absence of cardiovascular risk factors.¹⁷ Other investigators reported higher carotid intima-media thickness in HIV-infected subjects than in healthy controls, suggesting early atherosclerosis; duration of antiretroviral therapy and CD4⁺ T-cell percentage were associated with these changes.²³³

A prospective cohort study of HIV-exposed infants suggested associations of in utero antiretroviral therapy exposure with reduced left ventricular mass and dimension, reduced septal wall thickness Z-scores, and increased left ventricular fractional shortening and contractility up to 2 years of life.¹⁵² In a later study of this problem by the same group of investigators but with a more contemporary cohort of HIV-exposed but uninfected children, there was no evidence of cardiac toxicity of perinatal antiretroviral therapy exposure.¹⁵⁶ There were some subclinical differences in cardiac structure and function with certain antiretroviral medications and first trimester of pregnancy medication. The study authors proposed long-term follow-up of patients to determine future harmful effects of prenatal and postnatal antiretroviral drugs.

The increasing use of HAART and specifically of PIs in the pediatric HIV-infected population prompted careful management of associated hypercholesterolemia and hyperlipidemia. In univariate analysis, hypercholesterolemia in children with HIV infection treated with a PI regimen was associated with elevated systolic blood pressure but not with body mass.⁸⁴ Careful follow-up of lipid profiles should be evaluated routinely for HIV-infected children receiving antiretroviral therapy.

Renal Dysfunction

Renal disease is a well-known complication of HIV infection. HIV-1-associated nephropathy (HIVAN) is a clinical and renal histologic disease characterized by heavy proteinuria and nephrotic syndrome leading to rapid progression to chronic renal failure. The renal abnormalities described in HIVAN include nephritis (i.e., focal and segmental glomerulosclerosis and mesangial hyperplasia) and nephrosis.¹⁴ The immunopathologic characteristics of HIVAN include inflammatory infiltrations predominantly composed of activated T cells, with CD4⁺ T cells usually exceeding CD8⁺ T cells.²²⁹

Persistent metabolic acidosis associated with renal tubular disease and high anion gap acidosis has been reported for pediatric HIV infection.²²⁹ Renal disease in HIV-infected children often appears in concert with profound immunodeficiency and end-stage HIV disease. Because most pediatric patients with AIDS and renal disease have perinatally acquired HIV infection, the importance of congenital or early concomitant infections (e.g., CMV) has been postulated to affect pathogenesis. Host genetic factors also play an essential role in HIVAN.²²⁴

The nephrosis of HIV disease can be particularly difficult to treat in an already malnourished, hypoproteinemic, HIV-infected child. HAART is considered the best treatment for HIVAN. Corticosteroids in combination with HAART can be attempted. However, the risks associated with their long-term use in HIV-infected children should be balanced against their potential benefits.²²⁵ Many of the reported children with renal disease have associated growth failure. Nutritional supplementation and dietary restriction can offer supportive adjunctive therapy.

Bone Marrow Suppression

Hematologic abnormalities associated with HIV infection in children include leukopenia, anemia, and thrombocytopenia. The cause of neutropenia is often multifactorial in HIV-infected patients, representing the combined effects of systemic infection, medications, and the virus itself.¹⁰ Neutropenia often has been associated with circulating anti-neutrophil antibodies and may respond to blockade therapy with IVIG. Granulocyte colony-stimulating factor has been used successfully in drug-induced and HIV-associated neutropenia.^{111,112,195}

The anemia of HIV infection may be microcytic, hypochromic as seen in chronic infection, autoimmune with positive Coombs testing, or typical of nutritional deprivation (i.e., iron or vitamin B₁₂ deficiency). Determining the origin of anemia in AIDS is confounded by multiple cofactors that affect red blood cell counts, such as poor nutritional status and concomitant use of toxic therapeutic agents (e.g., zidovudine).

In adults and children, recombinant erythropoietin has been beneficial in treating anemia associated with antiviral therapy.¹⁹⁵ In developing nations, infant anemia of HIV exposure or infection coupled with acute local parasitic infections (e.g., malaria) can significantly affect infant morbidity. The risk of developing severe and potentially fatal malarial anemia is increased for HIV-exposed or -infected children with concomitant acute parasitemia compared with HIV-negative controls.²⁰⁸

Immune thrombocytopenia has been reported for 13% of children with symptomatic HIV infection with an onset as early as the first year of life.^{101,173} Thrombocytopenia in HIV-1-infected patients is multifactorial, including a direct effect of HIV-1 with a depressed platelet production due to HIV infection of megakaryocytes and peripheral destruction due to platelet-associated autoantibodies triggered by molecular mimicry between some HIV-1 peptides and membrane-associated platelet glycoproteins.¹⁵⁴ Therapy for thrombocytopenia in children and adults has included no intervention, platelet transfusions, systemic corticosteroids, IVIG, antiretroviral therapy, and in adults, IFN- α . Immune thrombocytopenia has resolved spontaneously in some children with simple supportive measures.

DIAGNOSIS OF HIV INFECTION IN INFANTS AND CHILDREN

Early Transmission to Fetuses

Human placenta plays a role in prenatal transmission of HIV infection from mother to fetus. Studies suggested that fetal infection can take place as early as 9 to 11 weeks' gestation.^{24,176} Preliminary examination of birth placental tissue from HIV-infected mothers in another study indicated that HIV core antigens could be detected in approximately 50% (23 of 51) of the cases studied and HIV antigens were localized in the Hofbauer cells.²⁷² Investigators documented that placental trophoblasts could be infected by CD4-independent isolates of HIV-1 in vitro.⁴ Placental cytokines and chemokines influence HIV replication in trophoblasts. Genetic analysis of HIV-1 sequences can verify the interaction of HIV-1 and placental tissue. The vertical transmission of HIV-1 is characterized by selection of genotype variants that escape the mother's immune system.⁵

An increase in the incidence of intrauterine fetal demise was demonstrated for HIV-infected pregnant women.⁷⁶ In HIV-negative fetuses, placental lesions associated with fetal demise were identified: abruption, infarction, and other infections (e.g., CMV). In HIV-positive fetuses, similar placental lesions could not be identified, and death was attributed to HIV infection of fetal tissue detected by in situ hybridization. Two hypotheses for transmission are proposed: direct cell-to-cell spread of HIV from infected maternal mononuclear cells through the placental cells and eventually to fetal tissue itself and infected maternal cells that gain access to the fetal circulation.

Methods for Diagnosing Infection in Children Older Than 18 Months

In children older than 18 months of age in whom maternal anti-HIV antibody no longer is a confounding variable, the conventional tests used to diagnose HIV infection in adults are applicable (Box 192B.2). Antibody detection tests, including the HIV rapid test, enzyme immunoassays (EIAs), Western blot analysis, indirect fluorescent antibody assay, and p24 HIV antigen (p24Ag) analysis, HIV culture, and HIV PCR assay, may be used.

The period between infection and detection of HIV antibody by a particular test is referred to as the *window period* for that assay. The window period for detection of HIV has been progressively shortened as EIA techniques have improved. Various generations of screening EIAs begin to detect anti-HIV antibody 2 to 6 weeks after HIV RNA is detected. EIAs that test for HIV-1 and HIV-2 are used for screening. Western blots, which have been used for confirmation of positive screening EIA results, become diagnostically reactive 5 to 6 weeks after infection. Aside from the HIV-1 Western blot, confirmation of HIV-1 infection can be achieved with qualitative or quantitative HIV RNA PCR or HIV DNA PCR analysis. Combined fourth-generation tests that detect HIV p24 antigen and HIV antibody have been used for initial screening, with confirmation of infection provided by HIV RNA PCR testing to reduce the window period for diagnosis with newer diagnostic algorithms.²⁰

Methods for Diagnosing Infection in Children Younger Than 18 Months

The clinical manifestations of HIV infection in children are varied and nonspecific and include chronic pneumonitis, failure to thrive,

BOX 192B.2 Guidelines for the Diagnosis of HIV Infection in Infants Born to HIV-Infected Mothers

Diagnosis of infants age <18 months: Virologic assays that directly detect HIV, preferably HIV RNA assays or the HIV DNA polymerase chain reaction (PCR) assay, must be used to diagnose HIV infection in infants age <18 months. A positive virologic test result should be confirmed by a repeat virologic test on a second specimen.

Diagnosis of infants age \geq 18 months: A positive HIV antibody test result with confirmatory Western blot or immunofluorescent antibody (IFA) assay or virologic assay is used for the diagnosis of infants age \geq 18 months.

Exclusion of HIV infection in infants: Definitive exclusion of HIV infection in non-breastfed infants is based on two or more negative virologic test results, one obtained at age \geq 1 months and one at age \geq 4 months, or on two negative HIV antibody test results from separate specimens obtained at age \geq 6 months.

Modified from Panel on Antiretroviral Therapy and Medical Management of HIV-Infected Children. Guidelines for the use of antiretroviral agents in pediatric HIV infection. <http://aidsinfo.nih.gov/contentfiles/lvguidelines/pediatricguidelines.pdf>; Department of Health and Human Services. Guidelines for the use of antiretroviral agents in pediatric HIV infection, 2012. <https://aidsinfo.nih.gov/guidelines/html/2/pediatric-arv-guidelines/0>.

hepatosplenomegaly, thrombocytopenia, and chronic diarrhea. For children younger than 18 months, a positive serologic determination of HIV is not accepted as indicative of HIV infection because of passive maternal antibody. Documentation of HIV infection in children younger than 18 months requires identification of viral components from blood. The most commonly used virologic assay in the United States is PCR for HIV DNA or RNA.²¹⁴

Pediatric PJP prophylaxis guidelines suggest that infants with two negative virologic assay results, both performed at 1 month or older and at 4 months or older, are not infected with HIV and that interruption of the therapeutic intervention is warranted.⁴¹ The early diagnosis of HIV-exposed infants has been improved for identification of HIV-infected children (as early as the first month of life) and for uninfected children labeled as seroreverters (as early as the fourth month of life). Schedules for testing of HIV-exposed infants vary nationally. However, advances in diagnostic technology allow for early testing of HIV-exposed infants, including shortly after birth through 14 days of life, at 1 to 2 months of age, and again at 3 to 6 months. Confirmation of negative virologic assay (e.g., HIV PCR) results can be performed with typical antibody testing when the child is 18 months of age.

The assays outlined earlier easily detect HIV-1 subtype B that is commonly found in developed nations. To detect non-B HIV infection in individuals from or in developing countries, HIV RNA PCR may be preferred because it has a lower rate of false-negative assay results compared with HIV DNA PCR. If non-subtype B HIV is suspected, use of HIV RNA testing that is sensitive for these subtypes (i.e., more sensitive RNA PCR assays or branched DNA assays that are commercially available in the United States) should be considered.

IMMUNOLOGIC AND CLINICAL MONITORING OF HIV-INFECTED CHILDREN

Laboratory monitoring of HIV-infected children is linked to variables that predict morbidity and mortality: CD4⁺ T-cell percentage and HIV RNA PCR assay results. Clinical evaluations should occur at a minimum of every 3 to 6 months or sooner if the patient has clinical signs or AIDS-defining events, and measures of CD4⁺ T-cell and HIV RNA PCR values should be performed. Because of variations across commercially available RNA PCR assays that may be as great as twofold, the HIV-infected patient should be tested with a single assay type. Recommendations for changes in treatment based on changes in CD4⁺ T-cell percentages or HIV RNA PCR should be undertaken in consultation with a specialist who routinely provides care to HIV-infected individuals.

Evaluation of the individual HIV-infected child for viral resistance can be accomplished with the use of commercially available phenotyping or genotyping assays. Studies should be performed in consultation with an HIV specialist. Depending on treatment regimens, most children also should have laboratory studies performed to assess their potential for developing treatment-induced toxicities, including bone marrow suppression, metabolic acidosis, dyslipidemia disorders, and pancreatitis. It is recommended that this cohort annually receive dental and ophthalmologic assessments and tuberculosis screening. Routine recommendations for childhood vaccine delivery are outlined later.

TREATMENT

Primary Anti-HIV Infection Treatment

Implementation of combination antiretroviral therapy consisting of at least three antiviral drugs has enhanced survival rates, improved immune status, and reduced opportunistic infections.^{23,102,179,228} Increased survival of HIV-infected children brings challenges in selecting successive new antiretroviral therapy regimens, and specific issues to address include short-term and long-term toxicities related to therapy and development of drug resistance.

The principles of therapy are similar for all affected age groups. Treatment should be aggressive and use multiple drugs as early in the course of the infection as possible to suppress viral replication fully, reduce development of resistant viral strains, minimize drug-related toxicity, and preserve immune function. Considerations specific to the pediatric host include early clinical severity of HIV disease, viral load, and level of immune suppression; availability of appropriate drug formulations and dosing; unique pharmacokinetics (e.g., body composition, renal excretion, liver metabolism, enzyme maturation); regimen potency, complexity, short-term and long-term toxicity potential; impact of changing therapy; comorbidities that affect drug choice; drug

interactions; and the ability of the parent or child to adhere to a prescribed regimen.

Guidelines for initiation of therapy are somewhat different for adults and children. Pediatric recommendations include initiation of therapy for all HIV-infected children, with the strongest support for the recommendation for symptomatic and immunosuppressed HIV-infected children and children younger than 12 months of age, regardless of clinical, immunologic, or virologic status. Current antiretroviral therapy is designed to target different steps in the replication cycle of HIV (Fig. 192B.4).¹³⁹

The Working Group on Antiretroviral Therapy and Medical Management of HIV-Infected Children recommends aggressive combination of at least three medications from at least two drug classes for initial treatment of HIV-infected infants, children, and adolescents. With improvements in treatment formulations, dosing recommendations for antiviral agents can change over time. Updated information on specific antiretroviral medications, including dosing and drug-drug interactions of antiviral agents, is provided in the guidelines from the Panel on Antiretroviral Therapy and Medical Management of HIV-Infected Children.²¹³

Inhibitors of HIV Cell Entry

Entry of HIV-1 into target cells begins with interactions of the viral envelope protein gp120 with CD4 and a chemokine coreceptor, usually CCR5 or CXCR4. The cellular receptors and structures in envelope proteins associated with membrane attachment and fusion are targets for therapeutic intervention.

Blockade of HIV by CD4-Receptor Inhibitors

CD4-based molecules can neutralize HIV by several mechanisms. Initial studies demonstrated the efficacy of soluble preparations of CD4 (sCD4) against HIV in vitro.^{126,240,277} A chimeric molecule consisting of

FIG. 192B.4 Inhibition of HIV-1 replication can be accomplished at different steps in the viral life cycle. (From Smith RL, de Boer R, Brul S, Budovskaya Y, van Spek H. Premature and accelerated aging: HIV or HAART? *Front Genet.* 2013;3:328.)

recombinant CD4 and immunoglobulin G (rCD4-IgG) was developed with an extended half-life and enhanced efficacy. Shearer and colleagues²⁵³ documented safety, evidence of placental transfer, and appropriate elimination after intravenous administration of rCD4-IgG2 in pregnant women. In a phase I/II study, 18 children infected with HIV-1 received single or multiple intravenous doses of rCD4-IgG2 and demonstrated evidence of antiviral activity and tolerance.²⁵¹

Certain small molecules may competitively inhibit viral entry by binding gp120, blocking the gp120-CD4 interaction. These small molecules in development as antiretroviral medications are thought to interfere with the gp120-CD4 interaction by altering the conformation of gp120 induced by CD4 instead of directly blocking CD4 binding.⁶⁵

Blockade of HIV by Chemokine Inhibitors

Agents that block CXCR4 and CCR5 are being evaluated in clinical trials. Concerns about the use of chemokine (i.e., coreceptor) inhibitors include the potential for unintended immune modulation and for viral escape to occur from tropism selection, with resultant disease progression.¹⁹⁴ Maraviroc, a first-in-its-class selective CCR5 coreceptor antagonist, received approval by the FDA for use in adults in August 2007. It is recommended as adjunctive therapy for combination antiretroviral regimens and targets treatment of CCR5-tropic HIV-1 (i.e., R5 virus). The most common adverse effects are cough, fever, upper respiratory tract infections, rash, musculoskeletal symptoms, abdominal pain, and dizziness.

Blockade of HIV by Interference With gp120-CD4 Interactions

Polyanionic compounds such as dextran sulfate and heparin inhibit binding of HIV to the cell membrane, targeting the V3 loop of gp120.¹⁹³ Because of their systemic toxicity, most of these compounds have been evaluated in clinical trials as topical microbicides to prevent sexual transmission of HIV in humans. Unfortunately, clinical trials involving polyanion-containing microbicide formulations demonstrated that these products were ineffective, and in some circumstances, they might have increased the risk of HIV-1 infection.²¹⁸ An additional substance, the green tea flavonoid epigallocatechin gallate (EGCG), binds to the CD4 molecule at the gp120 binding site, inhibiting gp120-CD4 interaction in a dose-dependent manner.²⁸² These adjunctive mechanisms to restrict HIV infection remain under development.

Blockade of HIV by Fusion Inhibitors

Fusion of the HIV envelope (i.e., glycoprotein gp41) with the target cell membrane is an important step in host cell infection. During fusion, the gp41 fusion peptide inserts into the target cell membrane, and gp41 heptad repeats (i.e., HR1 and HR2) alter their conformations to form a six-helix bundle. This process produces a fusion pore through which the HIV capsid passes into the target cell.

Fusion inhibitors represent the first class of entry inhibitors for which there is a licensed drug. Enfuvirtide (T-20) is a synthetic peptide that binds to the HR1 domain of gp41, prevents six-helix formation, and inhibits fusion.^{48,227} Enfuvirtide is approved for use in HIV-infected adults and children 6 years of age or older whose HIV infection has not been controlled by other anti-HIV drugs. Addition of enfuvirtide to an optimized background regimen of antiretroviral agents has demonstrated modest decreases of HIV viral load for long periods.²⁸⁴

Although enfuvirtide is FDA approved for use in children, it is not commonly used because of its high cost; need for twice-daily, subcutaneous injections; and high rate of injection-site reactions. The most common adverse effects include mild to moderate erythema, induration, pain, lymph node swelling, itching, and tenderness at the injection site. Other reported side effects are diarrhea, nausea, fatigue, headache, dizziness, peripheral neuropathy, and hypersensitivity reactions.⁶⁸ In the absence of a fully suppressive antiretroviral therapy regimen, mutations associated with resistance to enfuvirtide have been rapid.

Nucleoside Reverse Transcriptase Inhibitors

Nucleoside reverse transcriptase inhibitors (NRTIs) have no direct effect on HIV reverse transcriptase. After phosphorylation by the host cell kinases, they inhibit viral reverse transcriptase by competing with the natural substrate at the same binding site on the enzyme. With their

incorporation into the newly forming proviral DNA, further viral transcription is prematurely terminated.

Six NRTIs are licensed in the United States: zidovudine (ZDV), didanosine (ddI), stavudine (d4T), lamivudine (3TC), abacavir (ABC), and emtricitabine (FTC). They are also available in combinations (e.g., zidovudine + lamivudine, abacavir + lamivudine, abacavir + zidovudine + lamivudine).

Nucleotide Reverse Transcriptase Inhibitors

Nucleotide reverse transcriptase inhibitors (NtRTIs) function like the previously described NRTIs, but they do not require phosphorylation. Tenofovir disoproxil fumarate (tenofovir DF [TDF]) and tenofovir alafenamide (TAF) are orally bioavailable prodrugs of tenofovir. TDF has good in vivo potency against HIV-1 and hepatitis B virus (HBV).⁹⁶ TDF has long serum and intracellular half-lives that allow once-daily dosing.

High-dose TDF treatment has been associated with skeletal abnormalities in young animals²⁷⁵ and a significant decrease in absolute bone mineral density in HIV-infected children.⁹⁴ The changes in bone mineral density appeared to stabilize by 24 weeks of treatment, and none of the patients experienced fractures during the study period. US pediatric guidelines suggest judicious use in children and young adolescents because of unfavorable bone mineral density changes at a time when bone growth is so important. New-onset or worsening of renal impairment has been reported in adults and children receiving tenofovir and may be more common in those with higher tenofovir trough plasma concentrations.²³⁰

Oral-administration TDF is well absorbed and is so rapidly metabolized to TFV that TDF itself cannot be measured in blood, even when plasma is sampled within 5 minutes of administration.²¹³ TFV is the main compound measurable in plasma after TDF administration. From the bloodstream, TFV enters cells and is phosphorylated to the active agent tenofovir diphosphate (TFV-DP).

TAF also has good oral bioavailability.⁹ Within the enterocyte and liver, TAF is not metabolized to TFV as quickly as TDF. The plasma TFV concentration is much lower with administration of TAF compared with TDF, and the main component in plasma is the prodrug itself, TAF.²³⁴ Relative to TDF, TAF more effectively delivers TFV to cells throughout the body.⁹ A lower dose of TAF results in equivalent or higher concentrations of TFV-DP inside cells compared with the much higher doses of TDF needed to attain a similar intracellular TFV-DP concentration.

The key pharmacokinetic difference between TDF and TAF is that TDF results in a higher plasma TFV concentration compared with TAF, but when administered at FDA-approved doses, both result in equivalent intracellular TFV-DP concentrations.²³⁴ Because it is intracellular TFV-DP that suppresses viral replication, TAF should have antiviral efficacy equivalent to TDF, but it should avoid the toxicities that are specifically related to plasma TFV.

A combined product, Truvada, provides a preformed tablet formulation of FTC (200 mg) and TDF (300 mg) available for use once daily. Truvada is the recommended drug for HIV PREP.⁴⁶

Nonnucleoside Reverse Transcriptase Inhibitors

Nonnucleoside reverse transcriptase inhibitors (NNRTIs) work by binding directly to the reverse transcriptase enzyme, rendering it nonfunctional. Five available drugs in this class are approved for use in the United States: nevirapine (NVP), delavirdine (which is not recommended in pediatrics), efavirenz (EFV), etravirine (ETR), and rilpivirine (RPV). The major disadvantage of the two drugs widely used in pediatrics in this category, NVP and EFV, is the rapid development of resistance with resultant cross-resistance between the two drugs. ETR, a newer NNRTI, retains activity against NVP- or EFV-resistant viruses when used in a regimen that also contains darunavir or ritonavir and if the number of NNRTI resistance-associated mutations is limited.²² Additional NNRTIs are in development.²⁷⁸

Protease Inhibitors

PIs are relatively small peptides that share structural features with the substrates for viral protease. These molecules bind to and inhibit viral

protease, preventing the virus from maturing into an infectious virion. These drugs are extremely potent in reducing plasma RNA viral loads. They exhibit a high barrier for development of drug resistance. As a class, they interact with the hepatic cytochrome P450 enzyme system, and many induce their own metabolism. As a result, the potential for significant drug-drug interactions is considerable. Examples of these interactions include those with oral contraceptives, antituberculous drugs, antiepileptic drugs, some antihistamines, and methadone.

Adverse events of PI use include previously described metabolic complications (e.g., dyslipidemia, lipodystrophy, insulin resistance, gastrointestinal effects of nausea or diarrhea), higher pill burden than with NRTI- or NNRTI-based regimens, and poor palatability of liquid preparations. PIs approved for the treatment of HIV infection include saquinavir, RTV, lopinavir (LPV) plus RTV, indinavir, nelfinavir (NFV), atazanavir (ATV), fosamprenavir (FPV), tipranavir (TPV), and darunavir (DRV). Previously used amprenavir is no longer manufactured in the United States. Saquinavir, which has a high pill burden, must be boosted with another PI due to low bioavailability, and limited pediatric pharmacokinetics data, and indinavir, which has an unfavorable toxicity profile and limited pediatric pharmacokinetics data, typically are not used in pediatrics.

Integrase Inhibitors

Joining of the viral genome and the host's chromosomal DNA is the hallmark of a retroviral infection. Integrase, the enzyme that catalyzes this step of the HIV life cycle, is an effective therapeutic target. On binding to specific sequences in viral DNA, HIV-1 integrase catalyzes two consecutive steps during integration: 3' processing, endonucleolytic cleavage of the 3' ends of the viral cDNA, and strand transfer, achieved by ligation of the viral 3'-OH cDNA ends to the 5'-DNA phosphate of an acceptor DNA (i.e., host chromosome).²²¹

Several compounds have been developed to block integration at different steps. Compounds that inhibit integrase at its catalytic site with an effect on strand transfer, known as strand-transfer inhibitors (i.e., raltegravir [RAL], elvitegravir, and dolutegravir), are approved for use. Elvitegravir is available in a combination quad pill containing elvitegravir, a novel boosting agent with no antiviral activity (i.e., cobicistat), tenofovir DF, and emtricitabine. Dolutegravir is available in combination with abacavir and lamivudine.

Allosteric integrase inhibitors intended to interfere with the integrase-LEDGF/p75 interaction are being designed. These new inhibitors (i.e., LEDGINs) have an effect on 3' processing and strand transfer.¹⁶⁷ Long-acting antiretroviral agents such as cabotegravir, a novel parenteral integrase inhibitor similar to dolutegravir, are under investigation.¹⁷² In research studies, the agent has been packaged into nanoparticles, conferring an exceptionally long half-life of 21 to 50 days after a single dose.^{19,265}

Antiretrovirals available for use in the United States are listed at <https://aidsinfo.nih.gov/guidelines/html/2/pediatric-arv-guidelines/0>. Optimal antiretroviral combinations for children may be slightly different from those for adults. For infants, particularly those younger than 1 year, there is often a need to use very potent antiretroviral regimens for reduction of persistently elevated virus loads.^{163,211} In this scenario, four-drug combinations that include a protease inhibitor, two nucleoside analogues, and a nonnucleoside analogue such as nevirapine may be indicated.

The use of many antiretrovirals is limited in younger children (especially those younger than 4 years of age) because of the lack of liquid formulations. Prevalent combination antiretroviral regimens in pediatrics include one protease inhibitor drug such as ritonavir plus lopinavir or use of atazanavir or darunavir (in older children) in combination with a double NRTI backbone such as ZDV + 3TC, D4T + 3TC, ZDV + DDI, D4T + ABC, ABC + 3TC, or FTC or 3TC (in older children).

The PIs may be substituted by NNRTI drugs such as nevirapine or efavirenz (the latter in older children). In special circumstances, it may be necessary to boost the main PI with additional PIs such as ritonavir or saquinavir to achieve higher blood concentrations. For instance, this is the case of atazanavir when used with tenofovir. Additional boosting with 100 mg of ritonavir in the treatment of older children is often warranted.

Triple NRTI regimens may have a role in specific case scenarios, however they are less potent antiretroviral regimens. Specific antiretroviral regimens to be avoided include any type of single or dual therapy; efavirenz during pregnancy; atazanavir with tenofovir without ritonavir boosting; combinations of ZDV + D4T; DDC with 3TC, D4T or DDI; and D4T and DDI in pregnant patients.

US clinical trials are evaluating the pharmacokinetics of integrase inhibitors in children and the pharmacokinetics of R5 receptor blockers. Newer-generation NNRTI drugs such as etravirine or rilpivirine have not been evaluated in children, nor are there dosing recommendations for multiple antiretrovirals in children younger than 4 years of age. In resource-limited settings, treatment studies have demonstrated greater durability of virus load suppression in children treated with ritonavir plus lopinavir regimens compared with nevirapine-based regimens, although nevirapine has been associated with improved growth in this population.⁴⁹

Change in Therapy

The decision to change antiretrovirals varies slightly according to the pediatric guidelines employed. The decision mostly depends on the surrogate markers used. Most experts agree that indicators of treatment failure include progression of HIV disease, growth failure, development of opportunistic infections while on established therapy, decline in CD4 percentiles, development or worsening HIV encephalopathy, and significant increases in virus load.

Toxicities and Adverse Effects

Specific antiretrovirals have many complications and side effects. The most frequent toxicities of ZDV are hematologic, particularly anemia, and neutropenia. They may resolve with dose reduction. All NRTIs can cause some degree of mitochondrial toxicity. ZDV can cause myopathy, and peripheral neuropathy is seen with this drug and with DDI, D4T, and rarely, 3TC. DDI is associated with pancreatitis. D4T is associated with lipodystrophy, and in combination with DDI, it may induce liver fatty acid syndrome, particularly during pregnancy. Abacavir is famous for a fatal hypersensitivity reaction, which occurs in 1% of pediatric patients. It manifests as flu-like symptoms with or without a rash, abdominal pain, sore throat, and myalgias. If the drug has been interrupted in this scenario, shock will ensue when it is restarted.

The NNRTIs most commonly cause rashes ($\approx 40\%$) and have been associated with Stevens-Johnson syndrome. Efavirenz is teratogenic, and central nervous system findings such as dizziness, insomnia, and nightmares have been reported shortly after initiation of treatment with this drug. There is some concern about the prolonged use of nevirapine during pregnancy in patients with higher CD4⁺ T-cell counts who developed hepatic failure,¹²² but there is still controversy on the subject because additional studies have failed to demonstrate an association.⁶⁷

Protease inhibitors have multiple drug-drug interactions because of their cytochrome P450 metabolism in the liver. Their most common side effects are gastrointestinal symptoms. Hepatitis and hyperbilirubinemia also occur. In adults, they have induced lipodystrophy, diabetes, and increased atherosclerosis because of lipid abnormalities. These findings are beginning to be recognized in children, although complications occur less often. Indinavir may induce renal stones by precipitation of the drug in the kidneys or tubules. There are also concerns about the potential in children for osteopenia and osteoporosis induced by combination antiretrovirals or HIV disease itself.¹⁹¹

One recognized complication of potent antiretroviral therapy is IRIS. It occurs most frequently in patients who initiate treatment with lower CD4⁺ T-cell counts. It is attributed to a wide range of pathogens, and tuberculosis is a common underlying condition. The pathogenesis appears to be colonization with opportunistic pathogens when patients have moderate to severe immunosuppression. With the initiation of combination antiretroviral treatment and subsequent recovery of immunity to the organism, there is a paradoxical clinical deterioration due to a dysregulated immune response.

IRIS usually manifests in the first 6 weeks of antiretrovirals and may resolve with the use of steroids or temporary discontinuation of antiretroviral treatment. It is infrequently seen in pediatric HIV cases

in developed countries, particularly because children are treated earlier. However, it is prevalent in the developing world and may produce high morbidity and mortality rates.

Benefits of Therapy

Despite the complications and controversies, the benefits of antiretroviral treatment of children with HIV are overwhelming. In the United States, the annual mortality rate for pediatric HIV patients decreased to less than 1% as of 1999 due to the availability of treatment.^{104,129} HAART decreases the virus load, preserves and restores the immune function, decreases the risk of comorbidities, decreases hospitalizations, improves survival, improves quality of life, and restores hope to children and their families. Perinatally HIV-infected children who received antiretroviral treatment are now young adults attending college and preparing for an adult life.

Treatment very early in the perinatal period or in the acute stages of HIV infection has dramatically reduced viral reservoirs, a situation that may render the environment amenable to a functional cure. Pediatric studies of HIV perinatally infected infants treated very early with potent antiretroviral therapy¹⁶⁴ and studies of adult cohorts treated during acute infection²³⁷ have shown that very early treatment of HIV is associated with control and decrease of the viral reservoir burden, which is likely a predictor of long-term HIV control. Although the early treatment approach has not been shown to induce a functional HIV cure, it has been associated with an extended period of complete viral quiescence, also known as HIV-free remission (i.e., no detectable plasma HIV RNA).

Antiretroviral treatment improves immune reconstitution and immune preservation of infected individuals. It also prevents HIV dissemination in susceptible or infected individuals, and it can potentially provide a functional cure.

Immune-Based Therapies

The cardinal immune manifestation of HIV infection is development of progressive CD4⁺ T-cell lymphopenia with resultant clinical disease associated with severe immunodeficiency. Replacement of the CD4⁺ T-lymphocyte pool is therefore a logical approach for immune-based therapies.²⁵⁰

Immune modulators have been assessed as single therapeutic agents and in combination regimens in adult clinical trials. An immune-based therapy (IL-2) demonstrated CD4⁺ T-cell count increases but no clinical benefit in two large, randomized studies.¹ Other immune-based therapies (e.g., gene therapies, growth hormone, IL-7) are being studied and should be used in the treatment of HIV only in the context of a clinical trial. IFN- α initially was studied as a therapeutic agent for Kaposi sarcoma and had good response rates, but significant side effects limit its use in HIV infection. The utility of immune-based therapies in pediatric or adolescent HIV infection may include treatment of concomitant chronic hepatitis B and C virus infection and HIV-associated immune thrombocytopenia.⁵⁴

Chronic immune activation has been associated with poor outcomes for AIDS-defining and non-AIDS-defining clinical events and for persistent CD4⁺ T-cell depletion. The cause of chronic immune activation in well-controlled HIV infection in the era of combined antiretroviral therapy, aside from coinfecting pathogens, can include low-level viral replication and microbial translocation. Therapeutic interventions that target immune activation, including interfering directly with activation and inflammatory pathways, are being developed.²⁹ Long-acting, potent neutralizing monoclonal antibodies that have the potential to control HIV viremia in the absence of antiretrovirals are being studied.²⁷

Vaccines

Goals for the development of an HIV vaccine include prevention of persistent HIV infection, prevention of severe clinical disease (i.e., AIDS), and therapeutic immunization to control HIV infection. The first candidate preventive vaccines tested in human trials in the late 1980s were based on the HIV-1 envelope glycoproteins gp120 and gp160, an approach aiming to induce neutralizing antibodies. The major limitations of this approach were lack of neutralizing antibody activity against a diversity of primary patient isolates of HIV-1 because of genetic variation and structural complexity of the HIV-1 envelope glycoproteins and absence of envelope-specific cytotoxic T-lymphocyte responses.^{107,134,175}

More than 30 HIV vaccines have been tested in human trials.^{233,242} The vaccines produced disappointing results until a HIV-1 vaccine efficacy trial completed in 2005 in Thailand (RV144) showed that priming with a recombinant canarypox vector (vCP1521) and boosting with this vector plus bivalent gp120 protein (AIDSVAX B/E) provided partial protection against HIV infection in heterosexual men and women.²³² A subsequent study showed that the peak neutralizing antibody response (Nab) in RV144 was substantially weaker than the peak Nab response in a study of AIDSVAX B/E in injection drug users that showed no efficacy.¹⁹⁰ The results suggest that weak neutralizing antibody responses can be partially protective against HIV in low-risk heterosexual populations or that the efficacy seen in RV144 was mediated by other immune responses, alone or in combination with neutralizing antibodies.

Antigenically diverse viruses, including HIV, contain highly conserved exposed sites, usually associated with function, that can be targeted by broadly neutralizing antibodies, and advances in the field have enabled increasing numbers to be identified.²⁸ Molecular characterizations of the antibodies and of the HIV antigens that they recognize offer hope for the discovery of new vaccines and drugs.

SUBSECTION XIII Prion-Related Diseases

Transmissible Spongiform Encephalopathies (Creutzfeldt-Jakob Disease, Gerstmann- Sträussler-Scheinker Disease, Kuru, Fatal Familial Insomnia, New Variant Creutzfeldt-Jakob Disease, Sporadic Fatal Insomnia)

193

Gail J. Harrison • William J. Britt

The prion-associated, neurodegenerative diseases classified as transmissible spongiform encephalopathies (TSE) are Creutzfeldt-Jakob disease (CJD), Gerstmann-Sträussler-Scheinker disease (GSS), kuru, fatal familial insomnia (FFI), and sporadic fatal insomnia (SFI).¹⁵⁰ They represent a subset within a group of diseases that also have been termed infectious amyloidoses or cerebral proteopathies.^{80,175,224,283} The TSE diseases affect both humans and animals (Table 193.1). CJD is the TSE of most relevance to pediatrics at this moment, although kuru historically also affected children and adolescents and young adults at one time.⁸⁵ The other TSEs are known to affect only adults and the elderly (Table 193.2).

It has been shown that these neurodegenerative diseases are prion diseases, caused by disease-associated prion protein (PrP^D or PrP^{Sc}), a self-propagating beta sheet-rich aberrant conformation of the normal cellular self prion protein (PrP^C) with neurotoxic and aggregation-prone properties that is capable of misfolding the PrP^C molecules and producing progressive neurodegenerative disorders. These disorders are characterized by progressive cortical dysfunction and are linked to the accumulation of insoluble, proteinaceous aggregates of PrP^{Sc} in the central nervous system (CNS).^{98,106,204} (see Table 193.1). The abnormal PrP^{Sc} is the main component of the TSE agent, called the prion, and is responsible for the prion diseases.

HISTORY

TSE diseases were recognized only in domestic livestock in northern Europe until late in the 20th century. Scrapie, a disease of sheep, was described first in the mid-1700s.^{40,248} Farmers soon realized early that the agent responsible for scrapie was communicable and instituted control measures that included isolation and destruction of affected animals and herds.⁴⁰ Evidence suggests that the scrapie agent can persist in contaminated soil for at least 16 years, a finding that explains the

reported recurrences of this disease in flocks that had been culled decades earlier.¹¹⁶ Although farmers were aware of the communicability of scrapie between herds of sheep and had documented its spread among sheep, its transmissibility was not formally demonstrated until 1936.⁹¹ Shortly thereafter, scrapie developed in a flock of sheep that had been inoculated with a vaccine for louping that was ill prepared from CNS tissue derived from sheep that had been exposed to scrapie.^{40,248} Together, these reports provided definitive evidence of the transmissible nature of scrapie. The term slow virus disease was initially coined by veterinarians to describe the natural history of this curious group of diseases in domestic animals, which includes a prolonged incubation period measured in years and a relentlessly progressive clinical deterioration once symptoms appear.²⁵⁰ This term was used until the 1980s, when investigators began to consider that although the agent responsible for the spongiform changes in scrapie-infected mice was transmissible, it could not be classified as a conventional virus.

A decade earlier, the observational and laboratory studies of kuru, a progressive cerebellar ataxia and dementia occurring predominantly in adolescent and young adults of the Fore tribe in Papua New Guinea, provided an important piece of the puzzle of the etiology of this group of diseases.^{3,120} The natural history of kuru was described initially by Vincent Zigas and Carleton Gajdusek, who noted that the disease was associated with the ritual cannibalism practiced by the Fore tribe.⁸⁵ In 1959, an astute veterinary neuropathologist, William Hadlow, observed a striking similarity of the spongiform changes in the brains of patients with kuru to the brains of sheep with scrapie and suggested that these two diseases could be caused by similar mechanisms, possibly a transmissible agent.¹²⁹ Gajdusek and coworkers^{109–111} eventually demonstrated that the clinical and histopathologic findings of kuru can be transmitted to chimpanzees and other nonhuman primates by inoculation of brain tissue from patients with kuru. Interestingly, they initially thought that

TABLE 193.1 Naturally Occurring Transmissible Spongiform Encephalopathies in Humans and Animals

Host	Disease
Human	Kuru
	Creutzfeldt-Jakob disease
	Sporadic
	Familial
	Infectious or iatrogenic
	Variant Creutzfeldt-Jakob disease
	Gerstmann-Sträussler-Scheinker syndrome
Sheep, goats	Fatal familial insomnia, sporadic fatal insomnia
	Scrapie
Mink	Transmissible mink encephalopathy
Deer, elk	Chronic wasting disease
Cattle	Bovine spongiform encephalopathy, bovine amyloidotic spongiform encephalopathy
Cats, tigers, pumas, cheetahs	Feline spongiform encephalopathy

the experiment was a failure because the animals did not become symptomatic until 18 to 21 months after intracranial inoculation was performed, and later reports from this same laboratory indicated that almost 20 years elapsed between inoculation and the development of disease in some chimpanzees.^{16,40,85} Subsequent studies by other investigators demonstrated that brain homogenates from patients with CJD, GSS disease, FFI, or, most recently, variant CJD (vCJD) can transmit spongiform changes to nonhuman primates.^{24,30,222,260}

A variant of FFI, SFI, was identified in the 1990s and added to this group of transmissible neurodegenerative diseases.^{194,215}

The hypothesis that transmissible neurodegenerative diseases are caused by a protein was suggested first by Griffith¹²⁸ in 1967 and later more extensively developed by Prusiner²²² and coworkers. The claim that the etiologic agent of scrapie is an isoform of a normal host protein, PrP^C (prion protein) that can transmit disease in the absence of nucleic acid was met initially with great skepticism and even today continues to evoke debate.^{69,70,187,222} Over the next decade, the hypothesis that a protein can promote the formation of a polymeric fibrillary, insoluble plaque without the requirement of a nucleic acid–encoded a protein of an infectious agent was supported by studies from several laboratories. This hypothesis represented a paradigm shift in biology, and Stanley Prusiner was awarded the Nobel Prize in 1997 for his groundbreaking studies of prion diseases. Approximately 20 years earlier, Gajdusek had also been awarded a Nobel Prize for his description of the transmissible nature of kuru and similar diseases of the CNS.

An important chapter in the TSE saga was the appearance of “mad cow disease” (bovine spongiform encephalopathy [BSE]) in Great Britain in the mid-1980s; by the late 1990s, almost 200,000 diseased animals had been destroyed.⁵³ Mad cow disease was discovered in cattle in several European countries and later in the United States. Of greatest concern has been the transmission of BSE to more than 100 individuals in Great Britain and the report of at least 3 cases in France.⁵³ A significant increase in the incidence of TSE among elk and deer (i.e., chronic wasting disease) has been reported in wild deer herds in the midwestern United States and in wild game farms in the western states.^{195,284} Because of the concern that large numbers of human cases could eventually result from contamination of food products and pharmaceutical reagents with BSE or contact with contaminated tissue from deer or elk, there has been substantial interest in the diagnosis, treatment, and prevention of TSE and in surveillance for BSE in livestock.

EPIDEMIOLOGY AND NATURAL HISTORY

The epidemiology and natural history of human TSE spans a variety of geographical, cultural, and medical exposures (see Table 193.2). Clues

FIG. 193.1 Area and linguistic groups historically affected by kuru in the Eastern Highlands Province of Papua New Guinea. (From Whitfield JT, Pako WH, Collinge J, Alpers MP. Cultural factors that affected the spatial and temporal epidemiology of kuru. *R Soc Open Sci.* 2017;4:160789. Available at https://www.ncbi.nlm.nih.gov/core/lw/2.0/html/tileshop_pmc/tileshop_pmc_inline.html?title=Click%20on%20image%20to%20zoom&p=PMC3&id=5319347_rsos160789-g1.jpg.)

from molecular epidemiology and genetic mutations provide insight into disease origins, transmission, and expression.

Kuru

Although farmers and neuropathologists were well aware that scrapie is readily transmissible, the possibility that human TSEs also are transmissible was not demonstrated until Gajdusek and coworkers defined the natural history of kuru in the Fore tribe in Papua New Guinea^{3,289} (Fig. 193.1). Kuru was originally named after the shivering noted early in the disease when the patients were cold. It was seen most commonly in children, adolescents, and young adults of both sexes, as well as older women, but rarely if ever in older men (Fig. 193.2). The disease was common in the specific area, with an incidence of 1% in the Fore tribe, and was a significant cause of death in this population.³ Gajdusek carried out a detailed observational study of the Fore people, including their ritualistic endocannibalism or transumption of the bodies of the dead.^{108,289} This ritual included eating of body parts and homogenization of the brains of dead relatives in bamboo cylinders with use of crude hand tools. The brain was reportedly ingested as well as smeared over the body by relatives and other members of the tribe.²⁸⁸ During most of their childhood, the Fore children remained with their mothers and other women of the village, including the time spent preparing the brains of dead relatives for ritual endocannibalism or transumption. It is during this time that exposure to the agent responsible for kuru was thought to occur, either by ingestion of the contaminated brain material or through skin abrasions that were present secondary to the nearly universal scabies infestation. Those affected had cerebellar ataxia, tremors, and choreiform and athetoid movements. Kuru affected all ages of individuals, including children. Gajdusek observed three stages of kuru: the early ambulatory stage, in which the patient remained able to walk upright; the second sedentary stage, in which the patient was able only to sit; and the terminal immobile stage, in which the patient was unable to sit up independently.

Gajdusek and coworkers hypothesized that kuru is caused by an infectious agent and injected homogenates prepared from the brain of a deceased kuru patient into nonhuman primates; after an incubation period of more than 2 years, a disease similar to kuru was observed in the primates.¹⁶ After the transmissibility of kuru was demonstrated in experimental animals, several other TSEs were shown to be transmissible in nonhuman primates and other animals.^{16,48,83,264,266} Subsequent studies demonstrated that kuru could be transmitted to nonhuman primates

by oral ingestion of contaminated tissue.¹¹⁸ Although the origin of the TSE agent responsible for kuru in the Fore tribe is unknown, the most plausible explanation is that a spontaneous mutation in *PRNP*, the gene encoding the normal cellular PrP^C, resulted in a case of CJD with the abnormal isoform PrP^{Sc} in the Fore tribe that then was introduced and propagated in the population by ritual endocannibalism/transumption of their dead relatives.²⁸² After ritual endocannibalism/transumption was halted by the government of these districts in Papua New Guinea,

new cases of the disease disappeared; the last case of kuru in an individual younger than 30 years of age was reported in 1985.³ Cases of kuru have developed some 40 to 50 years after exposure to infectious material, illustrating the prolonged incubation period of these diseases.^{84,85,164} The last recorded case of kuru was reported in 2009, and no one in the area born after 1959 has developed kuru.^{85,87} The surveillance of kuru ceased in 2012, after 55 years of fieldwork started by Gajdusek and colleagues in 1957.

TABLE 193.2 Human Transmissible Spongiform Encephalopathies: Clinical and Diagnostic Criteria

Disease	Acquisition	Clinical Features
Kuru	Ingestion of or percutaneous inoculation with contaminated central nervous system tissue during ritual endocannibalism/transumption in the Fore tribe in Papua New Guinea First case reported in 1957 Last case reported in 2004 (last case identified was born before 1960 in Papua New Guinea)	Bimodal age distribution with disease in adolescents and in older adults Adolescents presented with ataxia and dementia with prominent cerebellar involvement Rapidly progressive disease
Creutzfeldt-Jakob disease (CJD)	85% are sporadic reported cases of CJD; first reported in 1921 5–10% are familial cases caused by a defined mutation in PrP ^C protein; first reported in 1924 <5% are secondary to infection or iatrogenic sources from neurosurgical procedures, injection of cadaveric growth hormone or blood product, or clotting factor transfusions; first reported in 1974 Sporadic CJD Definite Brain biopsy or postmortem examination shows plaques on histopathology and/or immunohistochemistry, and/or Western blot confirmed protease-resistant PrP, and/or presence of scrapie-associated fibrils, and/or RT-QuIC prion PrP ^{Sc} specific positive detection in cerebrospinal fluid (CSF), brain, or nasal olfactory mucosa Probable Progressive dementia, myoclonus, visual signs, cerebellar signs, pyramidal/extrapyramidal signs, akinetic mutism <i>plus</i> Electroencephalogram with periodic sharp wave complexes CSF positive for 14-3-3 protein assay Magnetic resonance imaging (MRI) high signal abnormalities in the caudate nucleus and/or putamen areas <i>plus</i> No alternative diagnosis found on routine evaluation Possible Progressive dementia with myoclonus, visual or cerebellar signs, pyramidal/extrapyramidal signs, akinetic mutism <i>plus</i> No alternative diagnosis found on routine evaluation Infectious/Iatrogenic CJD Progressive neurological/cerebellar syndrome <i>or</i> Criteria for definite or probable CJD met <i>plus</i> Recipient human cadaveric-derived pituitary hormone <i>or</i> Antecedent neurosurgery with a dura mater implantation Familial CJD Definite or probable criteria for CJD met Neuropsychiatric disorder <i>plus</i> Disease-specific PrP gene mutation <i>plus</i> First-degree relative with definite or probable CJD	Classic presentation of dementia and sensory abnormalities followed by loss of motor functions Rapid progression of symptoms with death usually occurring <6 mo to <1 y after onset Disease of late middle age except in cases acquired after iatrogenic transmission from neurosurgical procedures (strong) or possibly blood product transfusions (weak)
Variant Creutzfeldt-Jakob disease (vCJD)	First reported in 1996 Acquired through exposure to beef or beef byproducts contaminated with bovine spongiform encephalopathy (BSE); route of acquisition presumed to be oral (ingestion)	Presentation similar to CJD but disease progresses more slowly, with death occurring >12 mo after symptoms develop

TABLE 193.2 Human Transmissible Spongiform Encephalopathies: Clinical and Diagnostic Criteria—cont’d

Disease	Acquisition	Clinical Features
	vCJD Prominent neuropsychiatric symptoms, painful dyesthesias <i>plus</i> EEG periodic sharp waves <i>plus</i> MRI pulvinar sign in brain <i>plus</i> Florid plaques on brain biopsy neuropathology <i>plus</i> Detection of agent in lymphoid tissue <i>plus</i> Accumulation of protease resistance prion protein in brain <i>plus</i> Positive RT-QuIC* for PrP ^{Sc} in CSF or nasal olfactory brushings	Mean age of cases approximately 28 y, with documented cases in adolescents
Gerstmann-Sträussler-Scheinker syndrome (GSS)	First reported in 1936 Autosomal dominant inheritance with documented point mutations in PrP ^C gene	Disease of middle age, with mean age at onset of 45 y; motor abnormalities and progressive dementia
Familial fatal insomnia (FFI)	First reported in 1986 Autosomal dominant inheritance with point mutations in PrP ^C gene (missense mutation codon 178)	Disease of middle age; presentation includes insomnia, dysautonomia, and motor dysfunction
Sporadic fatal insomnia	First reported in 1999 No genetic mutations identified, but homozygosity at methionine 129 is characteristic	Presentation similar to FFI and neuropathologic changes similar

*RT-QuIC real-time quaking-induced conversion PrP^{Sc} prion-specific detection test.

FIG. 193.2 (A) Little girl in Papua New Guinea in 1957 has the early signs of kuru in the ambulatory stage. (B) The same girl 2 years later has advanced kuru in the sedentary stage. She is unable to sit or walk and is held in the arms of a family member. (C) In this photograph, taken in Papua New Guinea in 1957, five women standing in back have advanced kuru and require long walking sticks to support them while standing and to help them walk. The three young girls sitting in front also have kuru. Young children, adolescents, and older women were affected by the kuru epidemic more than other demographic groups. (From Gajdusek DC. Early images of kuru and the people of Okapa. *Philos Trans R Soc Lond B Biol Sci.* 2008;363:3636–43.)

Creutzfeldt-Jakob Disease

Four different modes of acquisition of CJD have been described: (1) sporadic (sCJD), which occurs worldwide at a rate of 1 to 2 cases per million population per year and equally in men and women; (2) classic (cCJD), which results from inherited or familial mutations in the *PRNP* gene (>30 mutations found so far); (3) iatrogenic (iCJD), acquired or infectious, which occurs after exogenous exposure to prion-contaminated material (e.g., after neurologic procedures, injection of growth hormone, transfusion of blood products); and (4) variant (vCJD), which is acquired through oral ingestion of meat contaminated with BSE. Variant CJD is distinctly different from the other forms of CJD in presentation and diagnosis^{92,93,303} (see Table 193.1).

Little is known about genetic or environmental factors that contribute to the development of sporadic forms of these diseases, although numerous epidemiologic studies have claimed associations ranging from ingestion of mutton to exposure to blood products after surgery or treatment for clotting disorders such as hemophilia.^{4,44,89,92,93,193} The risk of cCJD after blood product transfusion is theoretical, but the risk of iCJD is estimated to be 14% in recipients of blood transfusions from individuals who died of iCJD. Two reports of sCJD have been published recently.^{92,93,303} Common migratory scavenger birds, such as crows, may also play a role in the geographic spread of TSE diseases.²⁷⁷ Studies of CJD cases have revealed numerous genetic mutations in the *PRNP* gene associated with the development of disease, and they have been defined as genetic causes of CJD and other TSEs.¹⁵⁶

Polymorphism in the methionine at position 129 in the coding sequence of PrP^C is the genetic variation most commonly recognized as being associated with sCJD.²¹³ Homozygosity at methionine 129 of PrP^C is seen in 64% to 81% of patients with sCJD but in only approximately 39% of the general population; it is thought to predispose an individual to both iCJD and sCJD.^{2,213,295} Valine homozygosity at this position was associated more frequently with cases of CJD in which onset occurred before 40 years of age.² A retrospective analysis of a small number of patients with kuru revealed that all were homozygous for methionine at position 129 and all had more rapidly progressive disease with a shorter incubation period than did other patients with kuru from the same cohort.¹⁷³ In Papua New Guinea, Fore women who had survived exposure to contaminated material during the ritual cannibalistic feasts were shown to be more likely to be heterozygous at methionine 129 (76%) than similarly aged Fore women who had not been exposed to the cannibalistic feasts.¹⁹⁸ This result suggested that heterozygosity at methionine 129 provided a survival advantage.

Population geneticists have argued that haplotype diversity at codon 129 of *PRNP* (the gene that encodes the cellular prion protein) may have developed in response to an epidemic of prion disease. If so, this response would represent a recent balancing selection in humans.^{199,200} The codon at position 129 also appears to modulate the clinical course of inherited TSEs such as FFI, and patients homozygous for methionine at position 129 have a more rapid clinical course than do patients who are heterozygous at this codon.²⁰⁶ Polymorphisms in the PrP^C, including those that occur at position 129, have not been associated with the development of vCJD after exposure to BSE-contaminated material; in fact, all human cases in Great Britain have been homozygous for methionine at position 129.¹⁵¹ Heterozygosity at methionine 129 is thought to confer resistance by inhibiting PrP^C protein-protein interactions.²¹³ Sequence analysis of the *PRNP* gene from populations throughout the world suggested that the observed increased frequency of heterozygosity at position 129 could be explained by widespread cannibalism among primitive humans and selection of methionine 129 heterozygotes secondary to increased disease penetrance associated with exposure of susceptible methionine 129 homozygotes to prion-contaminated tissue.¹⁹⁸ This conclusion has been challenged by other investigators.²⁵²

Sporadic CJD is the most common TSE in humans and accounts for approximately 85% of all cases of CJD (see Table 193.1).^{44,156} It occurs worldwide at a rate of approximately 1 per million population.⁴⁴ CJD is a disease of late middle age, with a mean age at onset of 55 to 65 years. Cases of CJD range from 20 to 84 years, with the youngest patients being 16 to 18 years old.^{43,102,205} Little evidence exists for case-to-case transmission of CJD, with the obvious exception of iatrogenic transmission of CJD.⁶⁷ Vertical transmission of CJD in humans has not been reported. Two cases of sCJD, in contrast to vCJD, in patients with clotting disorders who received blood product transfusions have been reported.^{92,93,275} Anecdotal reports of occurrence of CJD in the spouses of individuals with CJD raise the possibility of horizontal transmission.⁴⁶ Alternatively, disease in spouses could result from shared environmental exposures. Sporadic cases of non-CJD TSE previously thought to be caused solely by genetic mutations have been reported, thus extending the spectrum of TSE in humans.^{176,194} With the exception of cases that can be linked to an inherited genetic mutation, no epidemics of CJD have been reported. This observation led British epidemiologists to suspect that a link exists between what was initially thought to be an increased frequency of CJD in young adults and the outbreak of BSE in the British Isles.^{6,15,90,123,276,293}

Genetic mutations in *PRNP* can result in a variety of inherited TSEs and are likely to account for the reported outbreaks of TSE in isolated populations. Because of the relatively late onset of disease even in patients with well-characterized mutations in *PRNP*, the possibility that TSEs are inherited diseases of the CNS was not considered until more recent studies of the host cell origin of prions and the discovery that a cellular gene encoded the pathogenic protein associated with TSE. Estimates from various studies suggest that between 5% and 15% of cases of CJD may arise from mutations in *PRNP*.⁴³ Genetic linkage studies have demonstrated that TSEs are inherited in an autosomal dominant fashion, an observation consistent with several studies in families with FFI and GSS.^{23,146,179,201} In addition, defined mutations in *PRNP* have been shown

to account for the increased rate of TSE in geographically or ethnically isolated populations, such as Libyan-born Jews, an ethnic group with an incidence of TSE almost 40 times greater than that observed in other populations.^{67,95,122,147,148,151,254} More than 20 mutations in *PRNP* have been described; they appear to be scattered throughout the gene. Reported mutations include both point mutations in the coding sequence changes, which result in amino acid substitutions, and octapeptide insertions.^{61,67,120,148,219,227} Because mutations in *PRNP* by definition are not present in sCJD, mutations of this cellular gene are not thought to play a direct role in the development of sCJD. The mode of acquisition of the TSE agent in these individuals has not been defined. In sporadic cases of CJD, the proposal has been made that spontaneous generation of the TSE agent could be occurring extremely infrequently and resulting in CJD. However, since scrapie was eliminated in sheep in New Zealand and Australia by culling diseased herds, spontaneous development of scrapie has not been described in those herds, suggesting that spontaneous development of the agent of TSE leading to scrapie in sheep is almost nonexistent.⁷⁰ In most cases, disease secondary to a genetic mutation in *PRNP* develops in patients of middle age, suggesting that although these diseases exhibit an autosomal dominance inheritance, the genetic background of the host contributes significantly to the observed phenotypes.

Before the 1980s, cases of TSE occurring in children and adolescents, with the exception of kuru, were either extremely rare or not recognized. In the late 1980s, cases of TSE resembling CJD were reported in young adults who as young children had received injections of human growth hormone prepared from cadaveric pituitary glands.^{39,48,50} The thought was that the practice of pooling pituitary glands from a large number of cadavers increased the risk of contamination of the preparation with prions from subclinical cases of TSE. More than 100 cases of TSE occurring after injection of contaminated growth hormone preparations have been reported.⁶⁶ Whether new cases of TSE will develop in adults who were given cadaveric growth hormone before the mid-1980s remains uncertain, but with a mean incubation period of 12 years in documented cases, it is unlikely that significant numbers of new cases will be reported.^{41,50} Other sources of TSE have included dura grafts, corneal transplants, contaminated stereotaxic neurosurgical equipment, and, more recently, blood transfusions.^{7,27,41,45,96,127,130,143,209,211,219,211} An alarming case of TSE occurred in a chimpanzee after the use of a stereotaxic electrode that 2 years previously had been used in a procedure involving a patient with CJD. Because this electrode had been decontaminated numerous times with conventional sterilization methods before its use in this experimental animal, this case illustrated the potential for the occurrence of iatrogenic transmission of TSE to humans undergoing neurosurgical procedures.¹¹⁹ Two confirmed and two probable cases of CJD occurring after receipt of blood transfusions have been described in Great Britain.¹³⁰ Studies of experimental models of TSE, primarily scrapie in mice, have shown that the scrapie agent initially amplifies in titer in spleen and regional lymph nodes and enters the CNS by a bloodborne route or by infection of the peripheral nervous system.^{1,158,160,163,172,188} In addition, studies in mice have demonstrated that brain tissue from animals injected with hamster scrapie can harbor the infectious agent for a prolonged time without evidence of disease.^{138,230} Even during a period of inactive persistence and replication, the scrapie prion could be detected, suggesting that transmission of prion disease by contaminated blood products or surgical instruments may occur even if screening assays for the detection of prions are mandated.²¹⁶ To further cloud the issue, other investigators have postulated that less virulent strains of prions can attenuate the virulence of other strains of prions, which then can be transmitted readily during asymptomatic periods.^{190,279} After transmission to a secondary host has occurred, the phenotype of the more virulent strain could be expressed. These findings are particularly worrisome because of the possibility that food products from cattle with subclinical BSE could continue to be consumed. Similarly, the possibility exists that the low incidence of vCJD in Great Britain, in spite of what most authorities consider was a much larger exposure to BSE before eradication of BSE-containing herds, can be explained by persistence of infectious agents in genetically resistant individuals or persistence in non-CNS organ systems.^{33,138}

Such studies raised the possibility that TSE could be acquired by transfusion of blood and blood products obtained from infected hosts,¹⁷⁴ although considerable controversy existed about the importance of this transmission route.^{92,93,135,303} Investigators argued that the risk was exceedingly small on the basis of experimental studies in rodents and epidemiologic studies involving patients receiving quantities of blood products, such as hemophiliacs. However, at least four patients are believed to have contracted CJD from blood transfusions and at least one from human plasma–derived clotting factor.^{1,34,37,99,135,271,273,294} BSE has been transmitted to sheep by blood transfusions, and buffy coat preparations have been shown to transmit TSE to experimental primates.^{29,145} The US Food and Drug Administration has recommended a very conservative policy for blood and blood products because of these theoretical concerns; more recently, this policy has been reinforced after reports of blood transfusion–acquired CJD.^{134,177,299} In addition to the exclusion of donors with symptoms consistent with TSE, individuals who lived in or visited Great Britain or other countries with BSE for a cumulative period of 3 months during the interval 1980 to 1996 are also excluded as donors (http://www.redcross.org/services/biomed/0,1082,0_557_00.html).

With the possible exception of kuru, little evidence was available previously to suggest that TSEs such as CJD could be acquired by ingestion of contaminated tissue.⁴⁴ This claim was challenged in the early 1990s by the reports of several young adults with CJD in Great Britain.^{90,293} The rate of CJD in England was found to be approximately 15-fold higher than in surveillance studies from previous decades.³⁹ In the years preceding this startling increase in the rate of CJD, the cattle industry in Great Britain was devastated by a spreading epidemic of BSE, a disease ultimately shown to be a TSE.^{132,251,291} A similar disease had been noted in domestic cats and in animals housed in zoos that had been fed British beef and beef byproducts.^{30,84,251} The first case of human disease thought to be associated with BSE, termed vCJD, was described in 1995, about 10 years after the first cases of BSE were reported in cows. However, more careful analysis suggested that the first cases of BSE probably occurred in the 1970s.^{251,293} During the ensuing years, investigators have closed the circle of evidence, showing that vCJD represents the transmission of BSE to humans, presumably by ingestion of contaminated beef or byproducts from BSE-infected cattle.^{78,140,250,253} These byproducts include many common household and medical products, such as gelatin in food products and in pharmaceutical capsules, bouillon cubes used for food preparation, and a wide variety of foodstuffs containing beef.

Although the origin of BSE is far from settled, most investigators concur that changes in the rendering of beef and sheep carcasses to remove fat as part of the preparation of meat and bone meal protein supplements in animal feeds led to the epidemic. Before the late 1970s, beef carcasses were heated and extracted with hydrocarbons such as chloroform to delipidate the homogenate.^{35,94,265,291,293} Omission of the hydrocarbon-extraction step apparently decreased inactivation of bovine prions, allowing introduction of this agent into the food products of British cattle. The epidemic began slowly in cattle, with the first case documented in 1986; by the mid-1990s, more than 3500 new cases of BSE were being reported each year. As a result of the BSE epidemic, 200,000 diseased cattle died from BSE and almost 4.5 million cattle were slaughtered preemptively, at a cost of approximately £4 billion, to curtail the epidemic.^{5,53,251,298} BSE also has been documented in US herds, resulting in a ban on exportation of beef to several economically important markets.²³⁴

As noted earlier, transmission to humans was suggested first in 1995 after three cases of CJD in young adults were reported; by 1996, additional cases of CJD in young adults were thought to have been secondary to transmission from exposure to beef from BSE-infected cows.⁷⁸ Of the initial 20 human cases, only one individual was older than 40 years of age, and the mean age was 28 years.^{6,223,276,279,301} Additional evidence from in vitro studies of the protein agents responsible for BSE and vCJD and from animal inoculation indicated that vCJD represented a human infection with the agent responsible for BSE.^{56,83,139,170} Because the BSE epidemic was recognized first in 1985, researchers argued that the incubation period was approximately 10 years. On the basis of studies in kuru and experimental animal models of TSE, this estimate

was determined to be dependent on exposure, genetic susceptibility, and other, as yet unrecognized risk factors.^{66,178} For this and other reasons, mathematical projections of the extent of the human epidemic have been based on theoretical estimates of exposure rates, possible dose-dependent incubation periods, and undefined host genes that might alter susceptibility to TSE. Even though most of these variables cannot be quantified, arguments have been put forth that the epidemic in humans has peaked and that the approximately 120 cases of vCJD resulting from consumption of contaminated beef represents the extent of human disease associated with BSE.^{117,279} In contrast, other models of the current data suggest that as many as 100,000 people may be affected. Perhaps the most compelling argument against such a large number of human cases has been the slowly evolving epidemic of vCJD in humans, with the number of new cases declining; however, several investigators have contested this hypothesis.^{76,117,279,292}

Gerstmann-Sträussler-Scheinker Disease

GSS disease is a rare, sporadic, autosomal dominant, neurodegenerative disease caused by mutations within the *PRNP* gene (most commonly a codon 129 PrP102L mutation).²³⁶ It is worldwide in distribution, with an incidence of one per 100 million (see Table 193.2). It was the first TSE for which a mutation in a gene encoding for the PrP was discovered. Originally reported by Gerstmann, Sträussler, and Scheinker in 1936, it was probably recognized earlier by Viennese psychiatrists. There can be marked phenotypic variability in presentation, even among families, but GSS often manifests with hereditary ataxia or dementia in older adults. Also, patients may exhibit ocular dysmetria, gait abnormalities, dysarthria, myoclonus, spastic paraparesis, parkinsonian signs, and hyporeflexia or areflexia in the legs.

Fatal Familial Insomnia

FFI is a rare autosomal dominant disease caused by a mutation in *PRNP* (most commonly in codon 178 at position 129M) (see Table 193.2). It occurs worldwide and causes insomnia, movement disorders, ataxia, dysarthria, dysphagia, autonomic hyperactivity, and dementia in older adults. It was originally called thalamic dementia until the term FFI was adopted in 1986. At least 100 affected families in Europe, the United States, Australia, Japan, China, and Morocco have been reported.¹⁷⁹

Sporadic Fatal Insomnia

SFI, a rare disease originally reported in 1999, exhibits phenotypes similar to those of FFI but without the family history or the FFI genetic mutation (see Table 193.2). Fewer than two dozen cases have been studied in several countries around the world. All cases have shown 129 MM homozygosity and propagating PrP^{Sc}.

ETIOLOGIC AGENT AND PATHOGENESIS

The TSEs are now known to be caused by prion proteins associated with identified specific genetic mutations of the prion protein gene *PRNP*. Each of the TSE diseases is associated with a specific genetic mutation, with variants. Human PrP has a common polymorphism residue 129 (encoding methionine or valine), and homozygosity confers genetic susceptibility to CJD. Heterozygosity at codon 129 confers survival advantage.

The protein aggregates characteristic of prion-associated TSE are composed of polymeric fibrils of a host-encoded protein that are deposited in several different regions of the CNS and within other organ systems, particularly in lymphoid organs. Amyloid may be present in TSEs, and its role in the pathogenesis of these diseases is uncertain. However, the symptoms associated with the spongiform encephalopathies arise from cellular and end-organ dysfunction associated with the abnormal deposition of an isoform of the normal cellular protein, PrP^C.^{14,40,79,224} The physiologic function of PrP^C remains incompletely defined, and no null alleles of the *PRNP* gene have been identified, raising the possibility that some of the symptoms associated with these diseases are caused by a loss of normal PrP^C function.¹⁹⁸ Although the biologic determinants of the phenotypic expression and variation of CJD are not clear, prions may exist as multiple prion strains or genotypes that influence disease expression, and prion propagation may also be

associated with production of toxic species that cause disease.^{81,113,154} Six subgroups (MM1, MM2, MV1, MV2, W1, and VV), based on prion protein codon 129 genotype and biochemical characteristics of PrP, have been proposed to correlate with transmissibility and with the clinical and pathologic features of CJD.^{22,121,240} The TSEs share several clinical features with other cerebral amyloidoses, and the insoluble protein aggregates exhibit biophysical properties similar to those of plaques found in Alzheimer disease, currently the most common cerebral proteopathy.¹⁰⁶ However, the TSEs can by definition be transmitted by parenteral inoculation or by other less efficient routes, such as ingestion of contaminated tissue from the nervous system. Therefore, prion diseases are believed to be unique infectious diseases.

The initial claim that TSE resulted from a transmissible protein was met with considerable skepticism, both because a paradigm of biology was challenged and because key elements of the supporting scientific data were incomplete. Most experimental studies have been performed with the agent responsible for scrapie in sheep, which was adapted for growth in mice and other small animals. Early studies arguing that the scrapie agent did not contain nucleic acid were based on studies in which the agent was inactivated with ultraviolet radiation. These studies did not exclude the possibility that the scrapie agent contained nucleic acid but instead suggested that if it did contain nucleic acid, the coding sequence was so limited that it could not encode any replicative functions.^{18,19,222} Later calculations based on inactivation by gamma rays suggested that the scrapie agent could contain between 2- and 4-kilobase pairs of DNA.²³⁷ Other experiments demonstrated that the infectivity of the scrapie agent could be eliminated or significantly reduced by treatment with agents that denatured proteins, such as guanidine hydrochloride, sodium hypochlorite (bleach), and proteases.²²²

Together, these data led several groups of investigators to postulate that the agent is an infectious protein.^{26,128,225} Prusiner²²² isolated an infectious fraction from a scrapie-infected hamster brain homogenate and obtained a partial amino acid sequence. This fundamental finding led to identification of the prion protein (PrP^C) and eventually to the finding that a cellular gene on chromosome 20, *PRNP*, encoded the transmissible agent that was responsible for the development of scrapie in mice and hamsters.^{15,72} Not all investigators have been convinced that the scrapie agent is an infectious protein, and some data have suggested that it is a small virus.^{187,189} Once the protein encoded by the *PRNP* gene had been identified and definitively linked to scrapie and other TSEs, many investigators thought that the pathogenesis of these diseases would be elucidated quickly. However, the pathogenesis remains uncertain, perhaps because of the inability to assign a function to the normal protein product, PrP^C. The conformation of the normal cellular form of PrP^C is primarily α -helical and is susceptible to protease digestion. Various functions have been proposed for the normal, nonpathogenic isoform of the cellular PrP^C, yet transgenic mice lacking the *PRNP* gene have a normal lifespan and exhibit only minor variations in normal sleep patterns.^{58,59,88,226} These mice are completely resistant to prion disease regardless of the source of exposure, a finding that is consistent with the hypothesis that PrP^C is necessary for the disease process associated with scrapie and other TSEs.^{1,58}

In contrast to the normal cellular form of PrP^C, which is composed of four α -helical domains, the pathogenic form of PrP^{Sc} (scrapie prion protein) exists in an extended beta sheet, is insoluble, and is partially resistant to protease digestion, as indicated by the designation PrP^{res} (PrP protease resistant). The partial resistance of PrP^{res} to proteinase K digestion is a characteristic that allows pathogenic prions to be detected in tissue specimens and has been widely used to identify products of the conversion reaction of PrP^C to PrP^{res}.^{197,242} The conversion of PrP^C to PrP^{res} represents a central paradigm of the prion hypothesis. It is thought to occur as the result of a process similar to crystal formation by nucleation (i.e., seeding the normal cellular pool of PrP^C with PrP^{res}) or, alternatively, by a template-directed misfolding of a normal cellular protein. Thus, PrP^{res} can be viewed as a transmissible, infectious agent that catalyzes the conversion of the normal cellular protein to a form associated with protein deposition in the CNS, cell death, and, eventually, clinical disease in the host.

The normal cellular protein, PrP^C, is a small membrane glycoprotein that is covalently linked to cellular membranes, including the plasma

membrane, by a glycosyl phosphoinositol (GPI) linkage.^{255–257} This cell surface form can be released by treating cellular membranes with phospholipases.²⁵⁵ A secreted form of the protein also is expressed. Genetic mutations in *PRNP* appear to predispose the protein to assume other topologies, including a transmembrane form.^{131,270} Membrane-associated forms are postulated to play an important role in the neurodegeneration associated with accumulation of the misfolded forms of PrP^C, and secreted forms can accelerate disease in a genetically susceptible animal.^{131,228} Chesebro and coworkers^{71,73,259} demonstrated that transgenic mice encoding a GPI-anchorless form of PrP^C generated an abnormal protease-resistant PrP^{res} that could be transmitted to other animals and induce formation of amyloid plaques but failed to cause clinical spongiform encephalopathy (scrapie equivalent in mice) in experimental animals. When the anchorless form was coexpressed with the wild-type form of PrP^C, accelerated disease was seen. Therefore, it appears that a cell surface-linked PrP^C is required for induction of disease, yet amyloid-like deposits can be formed from the secreted form of PrP^C, and disease can be induced when both secreted and wild-type PrP^C are expressed.⁷³ Consistent with this observation was the description of a transmissible PrP^C amyloid disease without spongiform encephalopathy after inoculation of tissue containing amyloid deposits from a patient with GSS without CNS spongiform degeneration.^{221,228} Together, these studies argue that PrP^C misfolding, protease resistance, and amyloid formation are sufficient to confer transmissibility to the PrP^{res} but may not, by themselves, be directly responsible for transmissible disease.

The challenge to existing paradigms of molecular biology and genetics, including self-replication of a protein, were quickly noted by investigators in this field. Several investigators had previously demonstrated that distinctive strains of the scrapie agent exist and that these strains induce definable and reproducible phenotypes of disease in experimental animals.^{20,32,54,55,159} These well-accepted and reproducible studies strongly argued for the presence of a genetic program in the scrapie agent that was most consistent with a nucleic acid-containing agent. More recently, several studies have suggested that the phenotypic behavior of scrapie strains may be entirely dependent on the pathogenic conformation assumed by the PrP^C when it is exposed to pathogenic forms of PrP^C, which in turn is dependent on its posttranslational modifications.^{21,64,65,262,279,280,285} Researchers argued that the phenotypes of scrapie strains are entirely dependent on the protein structure of PrP^C and are independent of any nucleic acid-encoded genetic trait. A second characteristic of etiologic agents of TSE that was difficult to ascribe to an infectious protein was the species barrier for transmission of prions. This characteristic was noted when the scrapie agent from sheep was first adapted to mice and then to other species, including hamsters. Other examples of a species barrier include BSE: 1000 lethal doses (as defined in cattle) must be given to a mouse to induce disease.²⁸⁶ The species barrier not only contributes to the absolute resistance of species to infection with prions derived from other species but also can lengthen the mean incubation period in a population. The species barrier often is invoked to explain the rarity of TSE, even in populations repeatedly exposed to TSE in other species (e.g., humans exposed to scrapie-infected sheep), and it may explain the relatively low number of human cases of vCJD that develop after exposure to beef contaminated with BSE.⁷⁸ A more worrisome aspect of the phenomenon of species barrier is that subclinical infections could result from exposure to BSE and subsequent transmission, leading to secondary cases with clinical symptoms.^{138,279} A proposed unifying explanation for the restricted transmission of prion disease between species argues that species restriction is related to the efficiency with which exogenous prions interact with endogenous host-derived PrP^C to form PrP^{res}.^{1,64,65,78,144,166,231,262,278}

Although considerable gaps in understanding of the infectious agent responsible for TSE persist and at times have contributed to the controversy that surrounds the infectious protein hypothesis, *in vitro* studies have shifted the view of the field toward the infectious protein hypothesis. For example, protease-resistant prions (PrP^{res}) that appear identical biochemically to PrP^{res} derived from infected brain can be produced in cell-free systems *in vitro*.^{1,64,165} However, these preparations at first could not transmit disease to uninfected animals unless they were supplemented with brain tissue derived from diseased animals, presumably because their titer was too low.¹³⁶ A more recent study using a system to amplify

prion production through sequential folding, sonication, and feeding of new substrate produced titers of in vitro–derived prions that could transmit TSE to susceptible animals and accelerate the development of symptoms in infected animals.⁶³ These results have provided compelling evidence for a mechanism of recruitment of cellular proteins by a misfolded protein and subsequent protein deposition as an etiology of diseases classified as TSE.

Although several mechanisms can be envisioned to explain how a misfolded host protein could lead to the recruitment and misfolding of additional copies of the protein, the process by which deposition of PrP^{res} might lead to disease remains unclear. Based on solid-state nuclear magnetic resonance and x-ray crystallography, the underlying structures of prion amyloids appear to share common structural features, and single molecular methods will continue to advance understanding of misfolding and aggregation.¹⁶⁹ There are several well-studied examples (e.g., cystic fibrosis) in which loss of normal protein function leads to the development of disease in humans.^{126,296} These diseases are associated with loss of function of an essential cellular protein. The accumulation of cellular proteins (e.g., amyloid accumulation secondary to overproduction of a normal protein) also can lead to disease and usually is associated with deposition and loss of organ function. In the case of TSE, the proposed mechanism for the generation of pathogenic prions appears to be fundamentally different: the conformational change from a predominance of α -helical PrP^C to PrP^{res} molecules containing extensive amounts of an extended beta sheet results in the accumulation of insoluble, protease-resistant proteins that can recruit additional normal cellular proteins into this conformation. In vitro cell-free systems and studies from kindreds with inherited TSEs such as GSS and FFI have shown that exposure to the misfolded prion protein (e.g., PrP^{res}) can result in this conversion.^{1,64,65,68,107,235} In genetic TSEs such as GSS and FFI, the genetic mutation is inherited as an autosomal dominant trait, and the PrP^{res} pathogenic form of the prion protein was shown to be derived from the mutant allele of an individual heterozygous for this allele.^{1,64,68} The energetics required for the conversion in conformation of PrP^C to PrP^{res} are thought to be unfavorable and could require a mutant template or perhaps a chaperone protein (protein X).^{64,157,164,267} Because the conversion reaction is essentially irreversible, this change in protein conformation results in accumulation of the insoluble and protease-resistant PrP^{res} protein. Arguments have been put forth that certain conformations of PrP^C favor the conversion to pathogenic forms of PrP^{res}; this would provide additional constraints on the expression of disease that could explain the non-PrP^C genetic contributions to disease susceptibility and provide a final common pathway for genetic and infectious forms of the disease.^{1,270} Several studies have argued that the various protease fragments generated after PrP^{res} treatment with protease K may be associated with different patterns of disease in the CNS; this could account for additional diversity in disease phenotype attributed to this single, small protein.^{216,217,279} Once the pathogenic PrP^{res} accumulates, additional newly synthesized molecules are converted into PrP^{res}, and clinical symptoms develop, depending on the site of cell loss in the CNS. Accumulation of the PrP^{res} isoform probably involves a combination of new synthesis of PrP^{res} and decreased clearance of the misfolded aggregate. Failure to clear the misfolded pathogenic isoform may ultimately be the major pathway leading to accumulation of PrP^{res} and disease.^{1,241} Finally, studies have linked copper binding to PrP^C with oxidation of the prion protein.^{1,38,232,245,297} Alternatively, a copper-containing prion complex localized to the synaptic junction could protect normal synapses from oxidants or perhaps play a direct role in copper metabolism or transport.^{153,245} Loss of normal prion function by misfolding could then lead to neuronal loss. The importance of these newly described characteristics of PrP^C remains incompletely defined at this time.

Although inoculation of a susceptible host with prion-contaminated cadaveric growth hormone or the use of contaminated instruments during neurosurgical procedures clearly can transmit CJD, the route of infection leading to vCJD is only assumed to be oral ingestion of contaminated beef, based on studies in nonhuman primates.^{27,30,279} As noted earlier, studies have demonstrated that other TSEs, including kuru, can be transmitted by oral ingestion of infectious material, but only with large inoculums and often requiring extended incubation

periods.¹¹⁸ Researchers have shown that 10 g of BSE-infected cow brain can infect and kill most mice.¹³ Even though, extrapolating from these data, a comparable dose required for human infection would be difficult to achieve, these findings demonstrate that the BSE agent can be transmitted by oral ingestion.

The pathway leading from ingestion of PrP^{res} tissue to deposition in the CNS has been shown to require local replication in lymphoid tissue, which is thought to be followed by bloodborne dissemination to the CNS.^{1,133,160,163} High titers of infectious prions can be found in liver and spleen as well as in the tonsils and other lymphoid tissue of the oropharynx and gut, suggesting that the titer of the infecting PrP^{res} is amplified in these tissues before spread to the CNS. In vCJD, PrP^{res} can be found in the tonsils at levels as high as 10% of the levels in infected brain.^{136,281} However, these findings were reported to be restricted to vCJD; this may reflect a characteristic of the PrP^{res} of vCJD or possibly the route of inoculation. Studies in mice have shown that performing splenectomy before inoculation with the scrapie agent can prolong the disease course, and subsequent studies have demonstrated the importance of replication in cells derived from bone marrow for neuroinvasion.^{75,155,167} Other studies have demonstrated that expression of PrP^{res} in the peripheral nervous system is sufficient to transmit disease, suggesting that direct hematogenous dissemination to the brain is not necessary for transmission of TSE.²²⁹ Prions are thought to replicate in these tissues before spreading to the CNS, and one study documented the presence of PrP^{res} in an appendix that was removed 8 months before the onset of TSE in the patient.¹³⁶ Although the B lymphocytes were once thought to represent a likely candidate for the cell transmitting the PrP^{res} to the CNS, studies have provided data inconsistent with this mechanism of transmission.^{11,52,82,163,207,208,247} There is evidence for the role of follicular dendritic cells in lymphoid tissue as sites of prion replication, and they may direct the prion to the CNS.^{155,167} Other investigators have suggested that unidentified host cell molecules may provide the necessary interactions with the prion molecule to permit their trafficking with migratory myeloid cells and, ultimately, entry into the CNS.¹⁸¹ Candidate molecules have included components of the complement system, based on the study of PrP^{res} in transgenic mice lacking specific complement components, perhaps secondary to the expression of Fcy and complement receptors CD21/CD35 by follicular dendritic cells.^{23,162,182}

PATHOLOGY

The pathologic findings of TSE include a hallmark triad of histologic findings: neuronal loss, proliferation of reactive astrocytes, and status spongiosis.¹⁷ *Status spongiosis* is a descriptive term for degeneration of neurons and collapse of the cortical cytoarchitecture leading to vacuolation of the neuropil.¹⁷ Amyloid plaques also are observed in some patients, and in some cases PrP^{res} is present in these plaques.^{17,57,161} Whether the distribution of spongiform lesions is related to the pathogenesis of these disorders or merely reflects the duration of disease before the onset of clinical symptoms is unknown; however, some TSEs, such as FFI, exhibit a preponderance of histopathologic changes in specific locations (e.g., thalamus).^{17,57,185,215,268} Descriptions of the neuropathologic process of vCJD have suggested distinctive histopathologic changes,²⁷⁹ including a distinctive plaque containing a central amyloid core and fibrillary periphery with extensive spongiform changes in the immediate periphery of the plaque (Fig. 193.3).^{103,151} The surrounding spongiform changes are proximal to the plaque, and the remaining neuropil is relatively intact.^{57,151} These findings are unique to vCJD cases and have not been seen in sCJD cases from outside Great Britain.^{56,152} Histopathologic lesions in the cerebral and cerebellar cortices, basal ganglia, thalamus, and brain stem also have been described.¹⁵² Involvement of the cerebellum appears to be more common in vCJD than in reported cases of sCJD, but this finding may be related to the differences in age at onset of disease in these two populations; findings from young patients with sCJD have suggested that these patients have a syndrome more closely resembling vCJD than sCJD in older patients.²⁵ Extensive widespread CJD findings that included involvement of cerebellar white matter, corticospinal degeneration, and ballooned neurons were also reported in an 11-year-old child who died of CJD after

FIG. 193.3 Microscopic appearance of a specimen from a person with Creutzfeldt-Jakob disease (CJD), which produces rapidly progressive dementia. The vacuoles in the cerebral cortical gray matter (arrowhead) represent the spongiform encephalopathy that occurs with CJD. There is marked gliosis in response to the neuronal loss as CJD progresses. CJD has the potential for infectious spread, but cases appear sporadically. The agent of CJD is a prion protein (PrP), a neuronal cell surface sialoglycoprotein. Disease results when the normal prion protein (PrP^C) undergoes conformational change to an abnormal form (PrP^{Sc}), which is protease resistant (PrP^{res}) and can accumulate and cause loss of neuronal cell function, vacuolization, and death. (From Klatt EC, ed. *Robbins and Cotran Atlas of Pathology*. 2nd ed. Philadelphia: Saunders; 2010.)

treatment with native human growth hormone.²⁰³ Finally, electron microscopic studies of plaques from vCJD brain tissue have suggested subtle but recognizable differences between plaques obtained from patients with vCJD and those from patients with CJD.^{103,107}

CLINICAL MANIFESTATIONS

Only the clinical manifestations of sCJD and vCJD are discussed in this chapter. The other TSEs, such as GSS and FFI, are diseases that are unlikely to be encountered in children, and kuru, a horizontally transmitted form of CJD, is no longer reported to be occurring (see Table 193.2). The interested reader is referred to referenced discussions of these diseases in adults and in the Papua New Guinea unique population.^{42,100,112,141,180,185}

Clinical signs and symptoms during the early stages of CJD are subtle and often complex and include both motor and sensory dysfunction.¹⁴¹ Abnormalities in gait, ataxia, vision problems, and complaints of headache, dizziness, and paresthesias often are noted.^{42,51,210,238} Intellectual dysfunction, including loss of memory, speech abnormalities, anxiety, and depression, also are often presenting complaints of patients with early stages of CJD.^{25,42,51} Neurologic abnormalities may include corticospinal tract dysfunction as manifested by hyperreflexia, spasticity, and extensor plantar reflexes. Visual disturbances include visual field abnormalities and, in some cases, cortical blindness. Seizures are not a frequent clinical symptom of patients with CJD. Presentation mimicking a stroke syndrome has also been reported in elderly adult patients.²⁴⁶ Other, less frequent findings include evidence of autonomic system dysfunction and, rarely, lower motor neuron disease.^{210,243} Although death secondary to complications associated with the vegetative state usually occurs within 1 year after onset of symptoms, a small percentage of patients exhibit a prolonged disease course.⁵¹

The clinical symptoms of vCJD are distinct from those of sCJD. This disease has been reported in an 11-year old child with neonatal growth hormone deficiency who was treated from infancy with injections of native human growth hormone, as well as in an adolescent; therefore, CJD or vCJD could potentially be encountered by pediatricians.²⁰³ The age range for reported cases of vCJD is 11 to 48 years, a distribution clearly outside that of sCJD. Symptoms included psychiatric and sensory disturbances such as dysesthesias and paresthesias with electromyographic evidence of denervation. Psychiatric symptoms included anxiety,

depression, anorexia, social withdrawal, and other nonspecific complaints. As the disease progressed, more familiar findings of TSE, including pyramidal tract dysfunction, rigidity, cerebellar dysfunction, and myoclonus, developed. Visual disturbances also were noted late in the disease. The duration of illness has exceeded 1 year in most patients with vCJD and death follows complications associated with the vegetative state. As noted earlier, the clinical presentation of sCJD in young individuals more closely resembles that of vCJD than that of sCJD in older individuals.²⁵ In these young patients, prion-specific proteins are present in brain, cerebrospinal fluid (CSF), and nasal olfactory brushings.

DIAGNOSIS

The diagnosis of CJD or vCJD requires a high index of suspicion and, in the case of vCJD, a history compatible with exposure to contaminated beef or beef byproducts or, possibly, a previous blood product transfusion from a high-risk area, neurosurgical procedure, growth hormone injection, or corneal transplantation. Routine laboratory findings are nonspecific and not helpful.^{92,93,274,303} No consistent reports demonstrate systemic or CNS inflammation. Therefore, routine laboratory analysis of CSF often is nondiagnostic. Laboratory tests, electroencephalography (EEG) and brain imaging can provide support for the diagnosis.

Laboratory Diagnosis

Assays for specific CSF protein biomarkers, such as the 14-3-3 protein, tau, or neuron-specific enolase, may provide helpful laboratory evidence of CJD or vCJD.^{124,125,149,168,244,302} Definitive premortem diagnosis requires biopsy tissue, and histopathologic diagnosis can be facilitated by use of PrP^{res}-specific antibodies in both immunocytochemistry and Western blot assays.^{8,57,279,281} The use of monoclonal antibodies specific for PrP^{res} has permitted a more thorough understanding of the distribution of prions in CNS and non-CNS tissue in patients with TSE. Hill and coworkers reported that tonsillar biopsy followed by detection of PrP^{res} by both Western blot and immunocytochemistry or PRNP sequencing is useful for establishing the diagnosis of vCJD disease.^{105,137} This approach has been particularly valuable for defining the incidence of vCJD infection in populations, such as has been carried out in studies in Great Britain.^{105,142} The National Prion Disease Pathology Surveillance Center (<http://www.cjdsurveillance.com>) offers diagnostic testing assays for 14-3-3 and tau proteins in CSF, PRNP sequencing, Western blot analysis to identify and characterize PrP, histologic processing of brain tissues, and expert neuropathologic consultation for patients with suspected CJD.¹¹³ More recently, in vitro prion formation using CSF has been shown to be very sensitive and specific for the diagnosis of prion disease.^{10,196,214}

A second-generation, highly sensitive real-time quaking-induced conversion (RT-QuIC) prion test has been developed and evaluated in more than 2000 patients to detect the specific target of prion protein PrP^{Sc}; this provides a more specific diagnostic test for CJD than surrogate biomarkers do. The RT-QuIC assay shows favorable diagnostic performance compared with surrogate biomarker tests for prion disease such as 14-3-3 and tau proteins; together with PRNP gene sequencing, it can be used to differentiate major prion subtypes, which can help predict the disease progression. This new test can provide an early and accurate diagnosis and may be used to diagnose CJD by testing CSF or olfactory nasal mucosa brushings from patients who present with clinical signs and symptoms consistent with CJD.^{28,104,171,212,218,300}

Neuroimaging

Imaging of patients with suspected prion disease has been extremely helpful in establishing the diagnosis of these rare diseases.¹¹⁴ Although computed tomography may reveal a variety of structural abnormalities, none is sufficiently specific to be considered diagnostic. In contrast, magnetic resonance imaging findings of increased T2 signals from the striatum and thalamus are specific for prion diseases, especially vCJD.^{12,101} Abnormal signals originating from the pulvinar in the posterior thalamus (pulvinar sign) are distinctive for vCJD and should be considered highly predictive for the disease.^{12,77,184} Other studies have shown lesions in the cortex and basal ganglia, without involvement of the thalamus, in patients with biopsy-confirmed CJD.^{202,269} Therefore, cortical signal

increases, as well as hyperintensities in the basal ganglia and the thalamus, may occur in patients with CJD.

Electroencephalography

EEG tracings from patients with CJD and vCJD are characteristic but not diagnostic. The classic findings are synchronous, bilateral biphasic or triphasic periodic sharp waves of 1 to 2 cycles per second on a background of generalized slowing. Repeat or serial tracings may be necessary to document these changes.^{31,74,258}

TREATMENT

No known treatments of TSE are licensed for medical practice. In vitro models of PrP^C folding have suggested that a variety of agents may limit production of pathogenic forms of PrP^{res} in neuroblastoma cells in vitro. Comprehensive reviews of treatment modalities have been published, and the interested reader is referred to these publications.^{62,272} Derivatives of Congo red, polyene antibiotics related to amphotericin B, branched polyamines, and phenothiazines all have been reported to exhibit some activity and to delay onset of disease in experimental animals.²⁷² To date, no evidence that any of these proposed therapies would be effective in human TSE has been reported. Small molecules that target protein misfolding are in preclinical development, as are adoptive immunotherapy techniques using transfer of CD4⁺ T cells.^{60,115,249}

Immunotherapy with antibody vaccines targeting prion disease-specific epitopes that are exposed in the misfolded PrP^{Sc} conformation, dendritic cell vaccines that use antigen-loaded dendritic cells with the ability to bypass immune tolerance, and adoptive transfer of physiologic prion protein-specific CD4⁺ T cells are in early development for treatment of prion diseases.⁶⁰ At least two reports have suggested that anti-prion monoclonal antibodies may offer a therapeutic approach to TSE. These reports suggested that anti-prion antibodies directed at cell surface PrP^C prevented infection of susceptible cells and also eliminated infection in a chronically infected cell line.^{97,220,287} These findings argue that impaired clearance of misfolded PrP^C contributed to disease in animals infected with PrP^{res} and that passive antibody therapy could potentially cure similar infections in vivo.⁶⁰ Treatment of mice with soluble lymphotoxin-β blocked follicular dendritic cell maturation and inhibited the development of scrapie in inoculated, susceptible mice, suggesting that interventions with agents that can block neuroinvasion may be efficacious.^{183,208}

PREVENTION

Because effective treatments of TSE are still undefined, prevention of disease remains the goal of current medical practice. Iatrogenic transmission of CJD has been reported in more than 250 patients around the world. Infection occurs after exposure during neurosurgical procedures (including dural grafts and stereotaxic electrodes), after exposure to contaminated CNS tissue in the form of growth hormone or gonadotropic hormone preparations, and after corneal grafting. These forms of iCJD have declined due to awareness and appropriate interventions to avoid these exposures in patients. Because transmissions by blood and blood products have been reported, the American Red Cross has placed restrictions on donors to exclude those who may have been exposed to agents or geographical locations associated with TSE. Cases of TSE that follow exposure to human feces, urine, or mucosal secretions have not been reported; therefore, current universal precautions employed in health care settings should suffice to prevent health care-associated transmission during routine care of patients with TSE. Recent evidence has shown shedding of PrP in olfactory nasal washings of patients with CJD, but transmission to health care workers or close contacts by contact with nasal secretions of patients with CJD has not been documented.^{28,212}

The infectivity category of brain, spinal cord, and eye tissues is high, compared with CSF, kidney, liver, lung, lymph nodes, spleen and placenta, which are likely to be low. However, some experts think that lymphoid tissue may be in the moderate to high category in some patients. All other blood products, tissues, and body secretions are believed to be in a low or no infectivity category, based on limited data on actual infectivity titers.²⁹⁰

Inactivation of tissue and fluid suspected of being contaminated with prions is problematic because they exhibit unusual resistance to conventional chemical and physical decontamination methods.²⁹⁰ Early studies indicated that subjecting prion-containing brain tissue to temperatures in excess of 360°C resulted in a reduction of only about 90% in infectivity.^{36,49} In addition, formalin- and glutaraldehyde-fixed tissue retains infectivity indefinitely, and CJD has been transmitted from paraffin-embedded tissue sections.^{46,47} Several different approaches for decontamination of prion-contaminated tissue and instruments have been proposed.^{186,233,239} Tissues such as brain, eyes, lymphoid tissue, and spinal cords from infected patients may have high levels of infectivity. Therefore, the tissues and instruments in contact with these tissues should be handled as highly biohazardous materials. Instruments should be cleaned with high concentrations of sodium hydroxide or undiluted sodium hypochlorite and then autoclaved at high temperatures for prolonged periods or, if practical, incinerated. The high concentration of prions in lymphoid and nervous tissue in these patients should be emphasized to anyone in contact with patients with TSE, and material that may be contaminated with prions should be handled in a rigorous manner to ensure safe disposal. There are also special procedures for autopsies and embalming and burial of patients with CJD. The World Health Organization (www.who.int) provides guidelines for infection control, including sterilization, disposal, and biocontamination for prevention of TSE in health care and surgical settings, in certain occupations, and after death. These guidelines are also endorsed by the US Centers for Disease Control and Prevention.²⁹⁰

No documented cases of TSE transmission after routine dental procedures have been reported in humans. However, invasive endodontic procedures involving contact with nerve rich dental pulp may theoretically transmit prions from affected individuals.²⁶¹ Universal precautions for dental procedures are currently recommended; however, if the patient in need of invasive dental procedures is suspected of having a TSE, then referral to a major medical center is advised for special precautions and single-use instruments.²⁹⁰

Genetic counseling may be helpful in familial disease in families with a PRNP mutation.¹⁵⁶

There is no licensed vaccine available against prion disease. However, protocols are being considered to develop vaccines with disease-specific epitopes specifically targeting the misfolded prion conformation associated with TSE diseases.^{192,191,263}

Prevention of prion-associated disease in individuals also may be genetic. A naturally occurring variant of the human prion protein that may completely prevent prion disease in exposed individuals has been discovered. This novel PrP variant has a single amino acid substitution of G to V at codon 127 (G127V, or PrP V127). It likely resulted from positive evolutionary selection during the kuru epidemic in Papua New Guinea. Studies in transgenic mice expressing different ratios of the variant and wild-type PrP indicate that presence of the PrP V127 variant is refractory to prion conversion and also acts as a dose-dependent inhibitor of wild-type prion propagation.⁹

Chlamydia Infections

Margaret R. Hammerschlag • Stephan A. Kohlhoff

Chlamydiae are obligate intracellular pathogens that have established a unique niche within the host cell. They cause a variety of diseases in animal species at virtually all phylogenetic levels. In 1999, Everett and colleagues^{48,55} reported a taxonomic analysis involving the 16S and 23S rRNA genes that found that the order Chlamydiales contained at least four distinct groups at the family level and that within the family Chlamydiaceae there were two distinct lineages; they suggested splitting of the genus *Chlamydia* into two genera, *Chlamydia* and *Chlamydophila*. This classification was not universally accepted, and it was agreed that the family Chlamydiaceae contains a single genus, *Chlamydia*.^{67,154} This position has been supported by additional data on *Chlamydia* genome sequences. The genus *Chlamydia* now contains 11 recognized species: *C. trachomatis*, *C. psittaci*, *C. pneumoniae*, *C. pecorum* (infects cattle, other ruminants, and koalas),^{48,55,154} *C. muridarum* (formerly the agent of mouse pneumonitis), *C. suis* (an important pathogen of swine), *C. abortus* (causes abortion in cattle and sheep; rarely has caused abortion in humans), *C. caviae* (formerly *C. psittaci* guinea pig conjunctivitis strain), *C. felis* (causes epidemic keratoconjunctivitis in cats) and *C. avium* and *C. gallinacea* (two new species causing infection in wild and breeding birds).⁵⁷ *C. trachomatis* and *C. pneumoniae* are the most significant human pathogens, and *C. psittaci* is an important zoonosis.

Recently, several chlamydia-like organisms that are endosymbionts of free-living amoebae have been identified.⁶⁸ These organisms, which include *Parachlamydia acanthamoebae*, *Simkania negevensis*, *Waddlia chondrophilia*, and *Neochlamydia hartmannellae*, have been termed *environmental chlamydiae*.^{68,112} Analyses of nearly full-length 16S rRNA gene sequences of these isolates showed that they clustered with other members of the order Chlamydiales but in a lineage separate from those of *Chlamydia* (16S rRNA sequence similarities of >88%). Data on the potential role of these organisms in human disease are limited. This bacteria-protista interaction might have been a driving force for the development of effective mechanisms by bacteria to survive phagocytosis by unicellular eukaryotes, which in turn may have been a first step in the evolution of intracellular bacterial pathogens of higher organisms.^{36,137}

Chlamydiae are characterized by a unique developmental cycle with morphologically distinct infectious and reproductive forms: the elementary body and the reticulate body. They have a gram-negative envelope without detectable peptidoglycan, although recent genomic analysis has revealed that both *C. trachomatis* and *C. pneumoniae* encode proteins forming a nearly complete pathway for the synthesis of peptidoglycan, including penicillin-binding proteins.^{93,136,138,151} This finding is the basis for the so-called chlamydial peptidoglycan paradox, given that it has been known for decades that chlamydial development is sensitive to β -lactam antibiotics.¹³⁶ An explanation for this has been recently described: Chlamydia species do produce a small amount of peptidoglycan during cell division that is necessary for proper localization of septal proteins.⁹⁷ Chlamydiae also share a group-specific lipopolysaccharide (LPS) antigen and use host adenosine triphosphate (ATP) for the synthesis of chlamydial protein.¹⁵¹ Although chlamydiae are auxotrophic for three of four nucleoside triphosphates, they encode functional glucose-catabolizing enzymes that can be used for the generation of ATP. As with peptidoglycan synthesis, for some reason these genes are turned off.¹⁵¹ All chlamydiae also encode an abundant protein, the major outer membrane protein (MOMP or OmpA), that is surface exposed in *C. trachomatis* and *C. psittaci* but apparently not in *C. pneumoniae*.¹⁵¹ MOMP is the major determinant of the serologic classification of *C. trachomatis* and *C. psittaci* isolates.

After infection develops, the infectious elementary bodies, which are 200 to 400 μ m in diameter, attach to the host cell by a process of electrostatic binding and are taken into the cell by endocytosis that does not depend on the microtubule system. Within the host cell, the elementary body remains within a membrane-lined phagosome. The phagosome does not fuse with the host cell lysosome. The inclusion membrane is devoid of host cell markers, but lipid markers traffic to the inclusion, which suggests functional interaction with the Golgi apparatus. The elementary bodies then differentiate into reticulate bodies that undergo binary fission. After approximately 36 hours, reticulate bodies differentiate into elementary bodies. At approximately 48 hours, release may occur by cytolysis or by a process of exocytosis or extrusion of the whole inclusion, with the host cell left intact. Chlamydiae also may enter a persistent state after treatment with certain cytokines such as interferon- γ , treatment with antibiotics, or restriction of certain nutrients. In the persistent state, metabolic activity is reduced. The ability to cause prolonged, often subclinical infection is one of the major characteristics of chlamydiae.⁸⁰

INFECTIONS CAUSED BY CHLAMYDIA TRACHOMATIS

Epidemiology

C. trachomatis infection is the most prevalent sexually transmitted infection (STI) and infectious disease in the United States today.²⁸⁻³⁰ In 2010, more than 1.3 million cases were reported to the Centers for Disease Control and Prevention (CDC).^{29,30} The prevalence of chlamydial infection is associated less with socioeconomic status, urban or rural residence, and race or ethnicity than are gonorrhea and syphilis. Infection with *C. trachomatis* tends to be asymptomatic and of long duration. If a pregnant woman has active infection during delivery, the infant may acquire the infection and, as a consequence, either conjunctivitis or pneumonia.^{28,53,74,76,157} Children also may acquire chlamydial infection as a result of sexual abuse.

Chlamydia trachomatis Infections in the Neonate

History

At the beginning of the 20th century, before expectant mothers were being screened for STIs, the term *ophthalmia neonatorum* was, for all practical purposes, synonymous with gonococcal conjunctivitis. As neonatal conjunctivitis came under control with silver nitrate prophylaxis, the importance of another form of ophthalmia neonatorum, *inclusion blennorrhea*, was noted. The relationship between maternal genital infection and conjunctivitis of the newborn associated with inclusion bodies within epithelial cells was established by Thygeson and Stone in 1942.¹⁷⁰ Respiratory infection in infants caused by *C. trachomatis* probably was reported first in 1941 by Botsztejn,²³ who described an entity that he called *pertussoid eosinophilic pneumonia*.

Epidemiology

The rate of cervical infection with *C. trachomatis* during pregnancy varies from 1% to 37%, with the highest rates occurring in women 25 years and younger. *C. trachomatis* infection is acquired by the infant from the mother during parturition, as demonstrated in multiple well-controlled prospective studies conducted in the 1970s and 1980s of maternal-infant infection in which infection occurred only in infants born to infected mothers.^{28,53,74,72,157} No convincing evidence demonstrates

horizontal transmission from mother to infant, from other family members to the infant, or from infant to infant after delivery. Infection after cesarean delivery, usually associated with rupture of the membranes, or infection through intact membranes is a rare event but may occur.¹³ The overall risk for an infant born to a mother with active chlamydial infection becoming infected at any anatomic site has been reported to be approximately 50% to 75% in various studies (Table 194.1).^{53,76,157} Infants can be infected at more than one site, including the conjunctiva, nasopharynx, rectum, and vagina. The most frequent clinical manifestation of neonatal chlamydial infection, inclusion conjunctivitis, has been reported to occur in 15% to 37% of infants born to mothers with untreated cervical chlamydial infection.^{53,76,157} The most frequent site of infection, however, is the nasopharynx, with 78% of infected infants having positive nasopharyngeal cultures in one study.⁷⁰ Approximately half of infants with inclusion conjunctivitis also will be infected in the nasopharynx. In only a minority of infants with nasopharyngeal infection does chlamydial pneumonia eventually develop; Hammerschlag and colleagues⁷⁴ found that pneumonia subsequently developed in only 4 of 12 infants (33%) with isolated nasopharyngeal infection. The overall risk for pneumonia developing in infants born to chlamydia-positive mothers has been reported to range from 1% to 22%.^{53,76,157}

Data on the risk for acquiring rectal or vaginal infection are more limited. Bell and colleagues¹⁴ demonstrated that perinatally acquired *C. trachomatis* infection may persist for months to more than 2 years. Twenty-two infants born to women with culture-documented chlamydial infection were monitored, and positive cultures from the nasopharynx and oropharynx in the infants were detected as late as 28.5 months after birth. Rectal and vaginal infections were asymptomatic and persisted for at least 1 year, which can become an important confounding variable when young children are tested for the presence of *C. trachomatis* during evaluation for suspected sexual abuse.

Conjunctivitis. *C. trachomatis* was the most frequent identifiable infectious cause of neonatal conjunctivitis, and conjunctivitis was the major clinical manifestation of neonatal chlamydial infection in the United States in the 1990s. The introduction of systematic screening and treatment of pregnant women has resulted in a dramatic decrease in the number of perinatal chlamydial infections, including conjunctivitis, in the United States.^{2,71} However, in countries in which pregnant women are not screened routinely, including many developing countries, *C. trachomatis* remains the most frequent cause of neonatal conjunctivitis.^{130,147,152,176,180,181} The incubation period of *C. trachomatis* conjunctivitis is 5 to 14 days after delivery or earlier if premature rupture of membranes has occurred. At least 50% of infants with chlamydial conjunctivitis also will have nasopharyngeal infection. The manifestation is extremely variable and ranges from mild conjunctivitis with scant mucoid discharge to severe conjunctivitis with copious purulent discharge, chemosis, and pseudomembrane formation. The conjunctiva can be very friable and may bleed when stroked with a swab. Eyelid erythema and edema frequently are present. A Gram-stained conjunctival smear initially may reveal a predominance of polymorphonuclear leukocytes. Chlamydial conjunctivitis needs to be differentiated from gonococcal ophthalmia in some infants, especially those born to mothers who did not receive any prenatal care, had gonorrhea during pregnancy, or abused drugs.

FIG. 194.1 Anteroposterior chest radiograph of a severely ill 1-month-old male infant with *Chlamydia trachomatis* pneumonitis. Diffuse interstitial infiltrates and hyperaeration with a flattened diaphragm are prominent.

An overlap in both incubation periods and clinical findings can occur. Bilateral infections are present in two-thirds of cases. A follicular reaction is not seen because infants younger than 3 months of age do not have the requisite lymphoid tissue present in the conjunctiva.

Pneumonia. As stated previously, approximately 70% of infected infants will have positive nasopharyngeal cultures, but most of these infections are asymptomatic.^{74,153} Chlamydial pneumonia develops in only approximately 30% of infants with nasopharyngeal infection.⁷⁴ In infants in whom pneumonia does develop, the manifestations and clinical findings are very characteristic.^{11,85,171} The children usually are seen initially when they are between the ages of 4 and 12 weeks. A few cases have been reported in infants as young as 2 weeks, but no cases have been seen in infants older than 4 months. The infants frequently have a history of cough and congestion, with an absence of fever. On physical examination, the infant is tachypneic, and rales are heard on auscultation of the chest; wheezing is a distinctly uncommon finding.^{11,85,171} No specific radiographic findings except hyperinflation are found (Fig. 194.1). Significant laboratory findings include peripheral eosinophilia (>300 cells/cm³) and elevated serum immunoglobulin levels. If cultures are performed, infants with *C. trachomatis* pneumonia

may remain symptomatic and shed the organism from the nasopharynx for protracted periods.^{14,71} Generally, infantile pneumonia caused by *C. trachomatis* appears to be self-limited. Most infants can be managed as outpatients, although a few cases of severe disease requiring hospitalization and assisted ventilation have been reported. *C. trachomatis* pneumonia in infants also appears to be associated with few sequelae, although data are limited. Rarely, infants with *C. trachomatis* pneumonia may have concomitant otitis media.¹⁷¹

Diagnosis of *Chlamydia trachomatis* Infection in Infants

The diagnosis of neonatal conjunctivitis cannot be made on clinical grounds alone. Significant overlap in both incubation period and clinical findings occurs with infections by other organisms, especially *Neisseria gonorrhoeae*. In a high-risk population, particularly infants born to women with no prenatal care, gonococcal ophthalmia must be considered seriously.⁷⁶ The incubation period for gonococcal conjunctivitis is usually 3 to 5 days, but it can be longer. The incubation period for chlamydial conjunctivitis is approximately 5 to 14 days. Most cases will be evident by the time the infant is 2 weeks of age, which is after the infant leaves the hospital. Epidemiologic clues can help the physician decide whether gonococcal ophthalmia needs to be considered. Hammerschlag and colleagues^{72,76} noted that seven of the eight infants with gonococcal conjunctivitis in their studies were born to mothers who had not received prenatal care. Five of these women were abusers of crack cocaine. Another epidemiologic clue is a history of gonorrhea or other STI during pregnancy. The clinical manifestation of *C. trachomatis* pneumonitis in infants is fairly characteristic, and clinical diagnosis may be established with a degree of certainty.

The gold standard for diagnosis of *C. trachomatis* infection in infants and children remains isolation of *C. trachomatis* by culture from the conjunctiva, nasopharynx, vagina, or rectum. Seven commercially available nucleic acid amplification tests (NAATs) have been approved by the US Food and Drug Administration (FDA) for the diagnosis of *C. trachomatis* infection (described in detail in the discussion on infection in older children and adolescents).³¹ None of these have been approved for use in children. However, available data suggest that NAATs are equivalent to culture for detection of *C. trachomatis* in the conjunctiva and nasopharynx of infants with conjunctivitis.^{83,181}

Treatment of Chlamydial Conjunctivitis and Pneumonia in Infants

Oral erythromycin suspension (ethylsuccinate or stearate) 50 mg/kg per day for 14 days is the therapy of choice for the treatment of chlamydial conjunctivitis and pneumonia in infants.^{12,28,71} Additional topical therapy is not needed. The efficacy of this regimen has been reported to range from 80% to 90%; however, as many as 20% of infants may require another course of therapy.^{12,71} Erythromycin given at the same dose for 2 weeks is the treatment of choice for pneumonia and results in clinical improvement and elimination of the organism from the respiratory tract. One small study evaluated azithromycin and found that a short course of azithromycin suspension, 20 mg/kg per day given orally as one dose daily for 3 days, was as effective as 2 weeks of erythromycin for eradication of *C. trachomatis* from the conjunctivae and nasopharynx of infants with conjunctivitis.^{107,78} The CDC included azithromycin as an alternative to erythromycin in the 2015 Sexually Transmitted Diseases Treatment Guidelines.²⁸

Treatment with oral erythromycin has been associated with hypertrophic pyloric stenosis in infants younger than 6 weeks who were given the drug for prophylaxis after nursery exposure to pertussis.^{37,89} Erythromycin is a motilin receptor agonist. However, a recent retrospective cohort study of children born between 2001 and 2012 performed using the military health system database found that infants prescribed azithromycin in the first 2 weeks of life were also at increased risk for development of pyloric stenosis.⁴⁴

Prevention and Control Strategies

Because *C. trachomatis* infections are transmitted vertically from mother to infant during delivery, several possible options for intervention exist. Prospective studies of mother-to-infant transmission of *C. trachomatis* have demonstrated that neonatal ocular prophylaxis with silver nitrate,

erythromycin, or tetracycline ophthalmic ointment does not prevent the development of chlamydial conjunctivitis.^{32,76} The most effective method of control of perinatal *C. trachomatis* infection is screening and treatment of pregnant women.^{71,79,128} In the 1980s, McMillan and colleagues¹²⁴ and Schachter and coworkers¹⁵⁸ reported that treatment of pregnant women infected with *C. trachomatis* with erythromycin resulted in a dramatic decrease in chlamydial infection (i.e., conjunctivitis and nasopharyngeal infection) in their infants in contrast to infants born to untreated infected women. The introduction of NAATs for diagnosis and the use of well-tolerated antibiotic regimens, including amoxicillin and single-dose azithromycin, have increased the efficacy of prenatal screening and treatment.²⁸ This approach has been validated by a dramatic decrease in perinatal chlamydial infection in the United States^{71,75} and a persistence of these infections in countries in which screening and treatment of pregnant women are not standard practice, such as the Netherlands, Ireland, India, and China.^{130,147,152,176,180} Rates of maternal chlamydia infections frequently exceed 20% in many nations in sub-Saharan Africa and Asia.¹ The Canadian Pediatric Society recently recommended that neonatal ocular prophylaxis for *C. trachomatis* and gonococcal infection be stopped and emphasized the importance prenatal screening and treatment; this program was implemented in 2016.¹³² The American Academy of Pediatrics is considering similar recommendations.

Infections in Older Children

C. trachomatis has not been associated with any specific clinical syndrome in older infants and children. Most attention given to *C. trachomatis* infection in these children has concentrated on its relationship to sexual abuse. Isolation of *C. trachomatis* from a rectal or genital site in children without previous sexual activity may be a marker of sexual abuse; moreover, evidence for other modes of spread, such as through fomites, is lacking for this organism.^{28,72,79,91-94} Perinatal maternal-to-infant transmission resulting in vaginal or rectal infection has been documented, with prolonged infection lasting for periods up to 3 years.^{14,155,157} This duration can be an important confounding variable in evaluation of possible sexual abuse in a young child.

Four studies examining the epidemiology of STIs in children and adolescents being evaluated for suspected sexual abuse have been published since 2005. Three were retrospective chart reviews, including one each from Vienna, Austria,^{103,106} Auckland, New Zealand,^{100,102} and Miami, Florida.¹⁶¹ Despite differences in populations and methodologies,^{161,163} the results of the retrospective studies were fairly consistent. Charts were examined from a total of 4350 children, who were seen over periods ranging from 4 to 7 years. Their ages ranged from 0 to 17 years, and most were girls. The prevalence of STIs, specifically gonorrhea and *C. trachomatis*, was low, ranging from 0.4% to 1.8%. These findings are consistent with earlier published studies.^{45,91-94} Because these were retrospective chart reviews, they had some major limitations. Inclusion criteria varied, and not every child or adolescent was tested for every STI. In the one prospective study, Girardet and colleagues^{61,60} examined children 0 to 13 years of age being evaluated for suspected sexual abuse or assault at seven tertiary care centers in the United States (in Houston, Texas, Atlanta, Georgia, Harrisburg, Pennsylvania, and New York City). All children were tested at multiple sites for *N. gonorrhoeae* and *C. trachomatis* by culture. Vaginal and urethral swabs and urine were also tested using two NAATs. A total of 536 children were enrolled, and 485 (90.5%) were girls. None of the 51 boys enrolled were positive for an STI. Overall, 40 (8.2%) of the girls were found to have one or more STIs. *C. trachomatis* was detected by culture or NAAT in 15 of the girls (3.1%) enrolled. Sixty percent of the children who were positive for *C. trachomatis* gave a clear, credible, detailed description of molestation.

In the setting of repeated abuse by a family member over a long period, the development of infection would be difficult to demonstrate. The 2015 CDC Sexually Transmitted Diseases Treatment Guidelines do not recommend that samples for culture of *C. trachomatis* be obtained routinely from the pharynx and urethra in children who are suspected victims of sexual abuse.²⁸ The major reasons are the low yield from the urethra, the tendency for longer persistence of perinatally acquired pharyngeal infection, and the potential confusion with *C. pneumoniae*.⁹

Genital *Chlamydia trachomatis* Infections in Adolescents

As stated previously, *C. trachomatis* is the most prevalent STI and infectious disease in the United States. At least 70% (930,000) of cases were among men and women between 15 and 24 years of age, with the highest rates in women 15 to 19 years of age.^{30,52} In sexually active adolescents, the prevalence commonly exceeds 10% and may exceed 20%.⁵² The case rate of infection in females 15 to 19 years of age was 3378.2 per 100,000, more than 4 times the rate in males of the same age (774.3 per 100,000).³⁰ The reasons for this gender discrepancy, which is seen in almost every age bracket, are not clear but may include better screening of female adolescents and increased susceptibility to infection in women. More than 70% of infections in women are asymptomatic. Reinfection is very common, with as many as 40% of adolescent women being reinfected, usually from an untreated partner, within 9 months.⁸ Women sustain a disproportionate share of the morbidity from these *C. trachomatis* infections through their well-known complications of pelvic inflammatory disease, ectopic pregnancy, and tubal factor infertility.²⁸ Although *C. trachomatis* infection can be treated effectively with antibiotics, infections may result in tissue damage even with appropriate antimicrobial therapy. Although most infections are asymptomatic, in men they can cause urethritis, and *C. trachomatis* infection is the most frequent cause of epididymitis in men younger than 30 years.²⁸ The symptoms of chlamydial genital tract infections are less acute than those of gonorrhea, consisting of a discharge that is usually mucoid rather than purulent.

Lymphogranuloma Venereum

Lymphogranuloma venereum (LGV) is an STD caused by the L1 to L3 serovars of *C. trachomatis* that are endemic in tropical and subtropical areas (e.g., parts of Southeast Asia, Africa, South America, India, and the Caribbean) but rare in the United States.^{16,28} About 20 cases of LGV have been reported in children. Fewer than 1000 cases are reported in adults in the United States annually. Recently a resurgence of LGV infections has occurred among men who have sex with men (MSM) in Europe and the United States. Some common characteristics of these outbreaks are (1) it affected predominantly white MSM, (2) it presented mostly as proctocolitis (with no inguinal syndrome), (3) individuals affected had very high HIV coinfection rates (about 70%), (4) patients often reported multiple sexual contacts met at casual sex gatherings, (5) 71% met partners at sex-on-premises venues or sex parties, and (6) 23% met partners on the Internet.⁶

LGV is a disease of the lymphatic tissue that has acute and chronic manifestations. Unlike other anogenital *C. trachomatis* infections, in which replication is confined to mucosal epithelial cells, LGV can replicate in macrophages and produce chronic invasive infection. Progression follows several defined stages, similar to syphilitic infection. The primary lesion of LGV is a small, inconspicuous, asymptomatic genital papule or ulcer that heals without a scar. Days to weeks later, unilateral acute lymphadenitis with bubo formation occurs at the site of lymphatic drainage of the primary lesion; acute hemorrhagic proctitis develops after a rectal lesion. Systemic symptoms can include fever, myalgia, or headache. Approximately one-third of inguinal buboes become fluctuant and rupture; the remainder involute slowly. Although most patients recover from LGV after this secondary stage, a small number develop a chronic inflammatory response with fibrosis (as a result of the persistence of *Chlamydia* organisms in anogenital tissues) that can result in chronic genital ulcers or fistulas, rectal strictures, or genital elephantiasis. In females, the vulvar lymph drains to the retroperitoneal nodes; thus they may not have inguinal lymphadenopathy but rather the genitoanorectal syndrome with rectovaginal fistulas and rectal strictures.

To our knowledge, cases in the pediatric population have not been reported since the emergence of the new clusters of cases in 2003. We reported a case of a 16-year-old boy with LGV proctocolitis after having receptive unprotected anal intercourse with a 30-year-old man he met on the Internet.⁶ This history was obtained after the boy was found to be HIV positive. The diagnosis of LGV, in particular when it presents with proctocolitis, relies on a high index of suspicion that would lead to emphasizing certain aspects of the history and ordering the pertinent

diagnostic tests. Many pediatricians and pediatric gastroenterologists might not be familiar with the entity and might not entertain it as a diagnostic consideration in pediatric patients. The diagnosis can be further suggested by *C. trachomatis* testing that involves culturing the organism or, more commonly, by NAATs. Currently available NAATs will not differentiate LGV from other *C. trachomatis* serovars.²⁸ NAATs for *C. trachomatis* are also not cleared by the FDA for testing rectal specimens. Trying to ascertain the *C. trachomatis* serovar for confirmation of LGV has therapeutic implications because a single dose of azithromycin is unlikely to eradicate the infection and a 3-week course of doxycycline is the preferred treatment.²⁸

Trachoma

Trachoma, the most important preventable cause of blindness in the world, is caused primarily by the A, B, Ba, and C serotypes of *C. trachomatis*.^{17,116} It is endemic in sub-Saharan Africa and Southeast Asia. The disease is spread from eye to eye through infected secretions. Flies are frequent vectors.

Trachoma begins as a follicular conjunctivitis, usually in early childhood. The follicles heal, leading to conjunctival scarring that may result in entropion, in which the eyelid turns inward so that the lashes abrade the cornea. It is the corneal ulceration secondary to the constant trauma that leads to scarring and blindness. Bacterial superinfection also may contribute to scarring. Blindness occurs years after the active disease.

Trachoma can be diagnosed clinically. The World Health Organization (WHO) suggests that at least two of four criteria must be present for a diagnosis of trachoma: (1) lymphoid follicles on the upper tarsal conjunctivae, (2) typical conjunctival scarring, (3) vascular pannus, and (4) limbal follicles.¹⁷ The diagnosis is confirmed by culture, microscopy, or NAAT for *C. trachomatis* performed during the active stage of disease. Serologic tests are not helpful clinically because of the long duration of the disease and the high seroprevalence in endemic populations.

Poverty and lack of sanitation are important factors in the spread of trachoma. As socioeconomic conditions improve, the incidence of the disease decreases substantially. The WHO recommends a single dose of azithromycin, 20 mg/kg (maximum, 1 g), for the treatment of trachoma in children. Numerous studies have demonstrated that mass community treatment with a single dose of azithromycin to all residents of a village dramatically reduced the prevalence and intensity of infection.^{17,116} This effect continued for 2 years after treatment, probably by interrupting the transmission of ocular *C. trachomatis* infection. Other important interventions include fly control, through providing pit latrines, and face washing, either alone or with topical tetracyclines.¹¹⁶

Diagnosis of *Chlamydia trachomatis* Infections

Culture remains the gold standard of diagnosis for detection of *C. trachomatis* from the vagina or rectum in prepubertal children. *Chlamydia* culture has been defined further by the CDC as isolation of the organism in tissue culture and confirmation by microscopic identification of the characteristic inclusions by fluorescent antibody staining using a species-specific conjugated monoclonal antibody.²⁸

The major advance in the diagnosis of *C. trachomatis* infection during the past decade has been the introduction of NAATs. These tests have high sensitivity, perhaps even detecting 10% to 20% more cases than is possible with culture, while retaining high specificity.²⁸ Three commercially available NAATs are approved by the FDA and available in the United States: polymerase chain reaction (PCR), transcription-mediated amplification (TMA), and strand displacement amplification (SDA).^{77,83} PCR and SDA are DNA amplification tests; both use primers that target gene sequences on the cryptogenic *C. trachomatis* plasmid, which has approximately 10 copies per cell. TMA is an RNA amplification assay. NAATs that are commercially available have FDA approval for cervical and vaginal swabs from women, urethral swabs from men, and urine samples from men and women. Several studies have demonstrated that self-collected vaginal swabs also are suitable specimens.^{28,77,83} *C. trachomatis* DNA and RNA may persist for 9 or more days after treatment.⁵⁶

Even though culture is considered the gold standard for detection of *C. trachomatis* in children being evaluated for suspected sexual abuse, *C. trachomatis* culture is not standardized or regulated in any way. Sensitivity may vary significantly across laboratories. Enzyme immunoassays (EIAs) are not acceptable as confirmatory tests and have been associated with false-positive results, especially when used with vaginal and rectal specimens.^{79,73,145} The methods used for culture confirmation became an issue when several large commercial laboratories started using an EIA instead of fluorescent antibody staining and visual identification of inclusions for culture confirmation. This has resulted in at least one “outbreak” of *C. trachomatis* infection in the evaluation of suspected sexual abuse among residents and staff of an institution for those with intellectual disabilities in Ohio in 1990.^{79,74} All of the “positive” cultures, mostly rectal specimens, were subsequently determined to be false-positive cultures resulting from carryover of fecal material and bacteria in the culture specimens. The major advantage of culture is that it is 100% specific; however, because confirmation depends on visual identification of inclusions, a subjective component exists that could lead to misidentification of artifacts as chlamydial inclusions. This appears to have happened in two pseudo outbreaks in other states, one in a residential institution⁶⁹ and one among children being evaluated for suspected sexual abuse.¹⁶² In the latter, specimens for culture were outsourced to a commercial laboratory.

NAATs are not currently approved for the detection of *C. trachomatis* in rectogenital specimens or urine from prepubertal children and in rectal specimens from adults.^{28,77} Several studies, predominantly from MSM, found NAATs to be sensitive and specific for detection of rectal chlamydial infection. Data on the use of NAATs for vaginal specimens or urine from children are very limited.^{28,77,80} To date, four studies have been published comparing NAATs to *C. trachomatis* culture in children being evaluated for suspected sexual abuse.^{18,61,60,101,122} They include the recent multicenter study by Black and colleagues^{18,19} that evaluated SDA and TMA. Girardet and colleagues⁶¹ and Kellogg and associates¹⁰¹ primarily evaluated girls, most of whom were postpubertal. Both studies used ligase chain reaction (LCR), which is no longer manufactured. Kellogg and associates¹⁰¹ also evaluated PCR in addition to LCR. These studies had major limitations, including failure to use an independent reference standard in estimating test performance, failure to separately analyze test performance by age and gender, and the fact that most of the girls were postpubertal and many were sexually active. The ages of the children ranged from 1 month to 17 years, with a mean age of 8.6 years, and 82.4% were female. Anatomic sites tested included vagina, cervix, rectum, pharynx, male urethra, and urine. The overall prevalence of *C. trachomatis* infection in these studies ranged from 6.6% to 8.3% by LCR or PCR and 0.8% to 5.3% by culture. Many discrepant results were found, especially between culture and NAATs, which were more frequent with rectal specimens, but the numbers of specimens from nongenital sites was too small to accurately assess the performance of the assays at these sites.

A CDC-sponsored multicenter study also evaluated the use of SDA and TMA using urine and genital swabs (vagina and urethra) in contrast to culture for diagnosis of *C. trachomatis* in children from birth to 13 years of age.¹⁹ Cultures for *C. trachomatis* were performed at the laboratories of each center, according to their own protocols. Culture protocols at all sites included the isolation of *C. trachomatis* in cycloheximide-pretreated McCoy cells, in shell vials or 24-well or 96-well tissue culture plates. The fixed monolayers were stained to detect chlamydial inclusions with fluorescein-conjugated *Chlamydia* genus-specific or *C. trachomatis* species-specific monoclonal antibodies. All samples were processed and tested according to manufacturers' protocols, except for the TMA tests, which were performed on previously frozen urine or swabs collected in BD ProbeTec sample collection medium. Test results that were positive by SDA for *C. trachomatis* were confirmed using in-house PCR targeting the *ompA* gene performed at the CDC. Of 485 female participants, 15 (3.1%) had a positive result for *C. trachomatis* by any test (1.4% by culture; 2.3% by vaginal NAAT; 2.7% by urine NAAT). All participants who had a positive vaginal culture for *C. trachomatis* also had positive urine NAAT. Two girls had positive *C. trachomatis* cultures from rectal swab specimens, but negative vaginal swab specimens by both culture and NAATs and negative urine NAATs. No discrepant results were found

in any of the participants tested by SDA and TMA for *C. trachomatis*. All *C. trachomatis*-positive results were confirmed by DNA sequence genotyping. The sensitivity of vaginal culture for *C. trachomatis* was 39% in all girls studied. In contrast, the sensitivities of urine and vaginal swab NAATs were 100% and 85% in all female children, respectively, for detection of *C. trachomatis*. The 2015 CDC Sexually Transmitted Diseases Treatment Guidelines recommend that NAATs can be used for detection of *C. trachomatis* in girls being evaluated for suspected sexual abuse, with important limitations^{28,159}:

1. Because the prevalence of *C. trachomatis* in this population is low, additional testing is probably necessary.
2. Extrapolation cannot be made from these results to other NAATs or used in specimens other than vagina and urine in girls.
3. Specimens should be retained for further testing.

Some available commercial NAATs, such as TMA (Aptima Combo 2 Assay), offer an alternative target confirmation method that can be used on the same testing platform; however, no data exist on the use of this confirmatory test in this setting. Additional options include sending blinded specimens to an independent or reference laboratory for confirmation testing, confirming an NAAT-positive result by culture test (requires a separate, invasive specimen), or using a second, alternative technology commercial NAAT. Specimens collected from children for forensic applications should be retained in the laboratory for purposes of additional testing, in accordance with local policies and procedures and recent recommendations by the CDC.²⁸ Several new NAATs have been approved by the FDA for use in adolescents and adults but are not approved for use in children. Limited data suggest that they should perform as well as TMA and SDA in vaginal and urine specimens from children.³¹

Treatment

Chlamydial infections in older children may be treated with oral erythromycin 50 mg/kg per day orally four times daily, with a maximum of 2 g/day for 7 to 14 days.²⁸ Children older than 8 years may be treated with tetracycline 25 to 50 mg/kg per day orally four times daily for 7 days. Azithromycin 1 g orally as a single dose also may be used in children who weigh at least 45 kg, are 8 years or older, or both.²⁸ However, there are no data on the optimum dose or efficacy of the recommended regimens of azithromycin in children. Follow-up is extremely important to ensure that the infection has been effectively treated. One must also be careful to exclude possible reinfection.

The first-line treatment regimen recommended by the CDC for uncomplicated *C. trachomatis* genital infection in men and non-pregnant women is azithromycin 1 g orally as a single dose or doxycycline 100 mg orally twice daily for 7 days. Alternative regimens are erythromycin base 500 mg orally four times daily for 7 days, erythromycin ethylsuccinate 800 mg orally four times daily for 7 days, and levofloxacin 500 mg orally once daily for 7 days. The high erythromycin dosages may not be well tolerated. Doxycycline and ofloxacin or levofloxacin are contraindicated in pregnant women; quinolones are contraindicated in persons younger than 18 years. However, use of levofloxacin offers no advantages over doxycycline. For pregnant women, the recommended treatment regimen is also single-dose azithromycin. Alternative regimens are erythromycin base 500 mg orally twice daily for 7 days, amoxicillin 500 mg orally three times daily for 7 days, erythromycin base 250 mg orally four times daily for 14 days, and erythromycin ethylsuccinate 800 mg orally four times daily for 7 days or 400 mg orally four times daily for 14 days. Amoxicillin at this dosage is as effective as azithromycin or any of the erythromycin regimens and is much better tolerated.

INFECTION CAUSED BY *CHLAMYDIA PSITTACI*

Human infection with *C. psittaci* was described first probably by Juergensen in 1874 or Ritter in 1876. Ritter described seven cases of an unusual pneumonia that appeared to be caused by parrots and finches that were caged in the study of his brother's home in Switzerland. After these reports, several outbreaks of a similar disease in Europe established the association with exposure to birds. The term *psittacosis* was coined by Morange in 1892 from the Greek word for parrots, *psittakos*.

Organism

C. psittaci is a diverse species that affects psittacine and nonpsittacine birds.² The known host range includes 470 avian species.^{27,30,87,140} Birds that have been reported to have *C. psittaci* infection contain six major domestic species: chickens, turkeys, Pekin ducks, Muscovy ducks, geese, and pigeons. Infections in these species have been associated with significant outbreaks in humans.^{26,30,164} In the past, chlamydial infection in psittacine birds was termed *psittacosis*, whereas disease in wild and domestic fowl was called *ornithosis*. However, because *C. psittaci* strains isolated from psittacine or nonpsittacine species have been shown to produce identical disease in birds of either grouping, this distinction is artificial. The more universally applicable term *chlamydiosis* can be usefully employed to describe chlamydial infections of all animal species. New molecular assays using different gene targets have identified two new avian *Chlamydia* species, *C. avium* and *C. gallinacea*.^{67,166} Both may have zoonotic potential in humans. *C. gallinacea* has been identified in chicken flocks in several European countries as well as Australia and China. Detection of infection with these species in humans may require development of new diagnostic tests because available EIA assays for *C. psittaci* will not detect antibodies to *C. avium* and *C. gallinacea*.¹⁶⁶

Epidemiology

Chlamydial infections in birds represent a biologic hazard to human health and economic loss to the poultry industry.^{27,30,164} *C. psittaci* has been recovered from symptomatic and apparently healthy birds. Infection principally involves the gastrointestinal tract, and the chlamydiae are shed in feces or through infectious respiratory tract discharges.¹⁷⁴ Clinically inapparent, latent infections may be the predominant state. Overt clinical disease may be activated by stress factors, including overcrowding, poor nutrition, other bacterial and viral infections, and transportation.

Apparently healthy birds shedding chlamydiae can infect other birds or humans through contact. Infectious chlamydiae in respiratory secretions or feces may remain viable for several months. Transmission of disease is mainly through aerosols of fecal or feather dust, but oral infection is an alternative route. Transmission through eggs has been shown in chickens, ducks, seagulls, and psittacine birds.¹⁷⁴ However, most infected eggs do not hatch. In the nest, parent birds may infect their young, which may carry the infectious agent for many years. Young birds are more susceptible to infection than are older birds, and some species seem to be more susceptible than others. Often, disease carriers may be identified by the transmission of disease to other susceptible birds or by the sudden death of young nestlings with apparently healthy parents.¹⁵²

From 2003 through 2010, 94 human cases of psittacosis were reported to the CDC, a dramatic decrease from 935 cases reported from 1998 to 2003.³⁰ Eighty-five percent of cases of psittacosis in the United States were associated with exposure to birds; 70% of these reported cases were the result of exposure to caged pet birds.¹⁶⁴ Individuals at highest risk for acquiring psittacosis included bird owners or fanciers and pet shop employees. Since 1984, several major outbreaks of psittacosis have occurred in the United States in turkey-processing plants, in which approximately 300 persons were infected. Workers exposed to turkey viscera were at the highest risk for acquiring infection.^{27,87} In 1995, the CDC investigated an outbreak of avian chlamydiosis in a shipment of more than 700 pet birds from a Florida bird distributor to the Atlanta area.¹³³ Affected birds included parrots, parakeets, finches, lovebirds, cockatiels, conures, and canaries. Clinical psittacosis or serologic evidence of *C. psittaci* infection was found in 30.7% of households with birds from the infected flock. An average of 21 days (range, 1–47 days) elapsed between purchase of the bird and the onset of symptoms. Most of the infected individuals had mild or asymptomatic illnesses. Among persons in exposed households, illness occurred more frequently if the recently purchased bird had become sick or had died. Kissing or nuzzling, handling, and feeding the bird all were significantly associated with the development of clinical psittacosis, but in contrast to earlier studies, cleaning the bird's cage was not. The risk for acquiring clinical psittacosis varied significantly by type of bird to which the individual was exposed. The attack rate was highest for individuals exposed to parrots.

Inhalation of infectious aerosols derived from the feces, fecal dust, or secretions of *C. psittaci*-infected animals is thought to be the primary route of infection. The source birds can be infected asymptotically or can show signs of infection, such as anorexia, ruffled feathers, depression, and watery green droppings. Psittacosis frequently is a systemic infection in birds, and the turkey strains can induce severe pericarditis.¹⁷⁴

Psittacosis is an uncommon occurrence in children. In a series of 135 cases from Australia observed during a 15-year period, the youngest patient was 17 years of age.¹⁸² Children may be less likely to be exposed to birds. Bird keeping is more commonly a hobby of adults, and the parents are the ones who usually clean the cage of the family's pet bird. An outbreak of psittacosis involving two adolescents was reported from a small village in Scotland. The source of the infection appeared to be the local pet shop, which had taken delivery of four lovebirds, two of which died shortly after arrival.¹³⁴

Clinical Manifestations

Infection with *C. psittaci* in humans may range from clinically inapparent to severe infection involving multiple organ systems, as well as pneumonia.^{10,54,133,182} Symptomatic *C. psittaci* infection in humans may present as two forms: a severe atypical pneumonia or pneumonitis and a systemic toxic or septic form without respiratory involvement. In both cases, fever, chills, muscle aches and pains, and severe headache are typical. Other manifestations may be diarrhea, nausea, and vomiting. The mean incubation period is 15 days after exposure (range, 5–21 days). The onset usually is abrupt, with complaints of fever, cough, and headache. The fever is high and frequently associated with rigors and sweats. The headache can be so severe that meningitis can be considered a possibility; 33% of patients in the Australian series underwent lumbar puncture.¹⁸² The cough usually is nonproductive, and rales may be heard on auscultation. Chest radiographs generally are abnormal, with variable infiltrates. Pleural effusions also may be present. In contrast, most of the individuals in the Atlanta outbreak had very mild disease characterized by fever, headache, and cough.¹³³

Laboratory Findings

The white blood cell count usually is not elevated, but mild leukocytosis may be present. Almost 50% of patients in the Australian series had abnormal liver function test results, including elevated levels of aspartate aminotransferase, alkaline phosphatase, and bilirubin.¹⁸²

Diagnosis

The CDC and the Council of State and Territorial Epidemiologists have established national case definitions for epidemiologic surveillance of psittacosis. The updated case definitions were published in 2010.¹⁶⁴ A patient is considered to have a confirmed case of psittacosis if clinical illness is compatible with psittacosis and the case is laboratory confirmed by one of two methods: isolation of *C. psittaci* from respiratory specimens (e.g., sputum, pleural fluid, or tissue) or blood, or a fourfold or greater increase in antibody (immunoglobulin G [IgG]) against *C. psittaci* by complement fixation or microimmunofluorescence (MIF) between paired acute- and convalescent-phase serum specimens obtained at least 2 to 4 weeks apart. A patient is considered to have a probable case of psittacosis if the clinical illness is compatible with psittacosis and one of the two following laboratory results is present: supportive serology (e.g., *C. psittaci* antibody titer [IgM] of 32 or greater in at least one serum specimen obtained after onset of symptoms) or detection of *C. psittaci* DNA in a respiratory specimen (e.g., sputum, pleural fluid, or tissue) through amplification of a specific target by PCR assay.

Most diagnoses are established by clinical presentation and positive antibodies against *C. psittaci* in paired sera using MIF methods. The MIF is more sensitive and specific than the previously used complement fixation tests; however, some cross-reactivity occurs with other chlamydiae (i.e., *C. pneumoniae*, *C. trachomatis*, and *C. felis*), so a titer result less than 1:128 should be interpreted with caution.¹⁷⁵ Acute-phase serum specimens should be obtained as soon as possible after the onset of symptoms, and convalescent-phase serum specimens should be obtained at least 2 weeks after the first specimen. Because antimicrobial treatment can delay or diminish the antibody response, a third serum sample

4 to 6 weeks after the acute sample might help confirm the diagnosis. To increase the reliability of serologic results, acute and convalescent sera should be analyzed simultaneously at the same laboratory.

C. psittaci also can be isolated from the patient's sputum, pleural fluid, or clotted blood during acute illness and before treatment with antimicrobial agents. Although *C. psittaci* will grow in the same culture systems used for the isolation of *C. trachomatis* and *C. pneumoniae*, very few laboratories culture for *C. psittaci*, mainly because of the potential biohazard.

Real-time PCR (rt-PCR) assays have been developed for use in the detection of *C. psittaci* in respiratory specimens.^{10,125} These assays can distinguish *C. psittaci* from other chlamydial species and identify different *C. psittaci* genotypes. Although the assays appear to be highly sensitive and specific in avian samples, they have not yet been validated for use in human samples. Because proper sample collection techniques and handling are critical to obtain accurate test results, clinical laboratories performing these tests should be contacted directly for specifics on specimen submission.

Information about laboratory testing is available from state public health departments. Few commercial laboratories provide MIF testing, and manufacturing problems in 2009 resulted in limited availability of the MIF testing kits. Certain laboratories accept human specimens to confirm *C. psittaci* infection through culture, MIF, or PCR (Table 194.2).

Treatment

The recommended treatment of psittacosis in adults and children older than 8 years of age is tetracycline 500 mg orally four times daily for 7 to 10 days.¹⁶⁸ Erythromycin 50 mg/kg per day up to 2 g/day, for 7 to 10 days also can be used. The experience in the Australian series¹⁸² and anecdotal reports suggest that tetracycline may be more effective than erythromycin. The initial infection does not appear to be followed by long-term immunity. Reinfection and clinical disease can develop within 2 months of treatment; two well-documented cases of reinfection are reported in the literature. A pet shop employee had two episodes of psittacosis 11 months apart. Each episode met the CDC's confirmed case definition.²⁶

INFECTION CAUSED BY
CHLAMYDIA PNEUMONIAE

Organism

The first isolates of *C. pneumoniae* were obtained serendipitously during trachoma studies in the 1960s.⁶⁴ After the recovery of a similar isolate from the respiratory tract of a college student,^{66,169} the designation TWAR was applied, which refers to the first two isolates, TW-183 and AR-39. On the basis of inclusion morphology and staining characteristics in cell culture, *C. pneumoniae* initially was considered a *C. psittaci* strain. Subsequent analysis, however, has demonstrated that this organism is distinct from both *C. psittaci* and *C. trachomatis*.^{24,65} Sequencing has revealed that *C. pneumoniae* differs significantly from *C. trachomatis* in several areas. *C. pneumoniae* encodes 21 polymorphic membrane proteins versus 9 in *C. trachomatis*. Polymorphic membrane proteins may be surface exposed in *C. pneumoniae*.^{96,151} Ultrastructural studies have demonstrated an elementary body morphology distinct from that

of *C. trachomatis* and *C. psittaci* (Fig. 194.2).³⁴ However, some isolates of *C. pneumoniae*, including IOL-207, have been found to have round elementary bodies.^{25,141,144} Thus it may not be a consistent species characteristic. At this point, a strain-typing system for *C. pneumoniae* has not been developed. A plasmid has been detected in a single isolate obtained from a horse but not from any human isolate of *C. pneumoniae*.

Epidemiology

C. pneumoniae appears to be a common human respiratory pathogen. The organism also has been isolated from nonhuman mammalian species, including a horse, koalas, bandicoots, and reptiles and amphibians, although the role these infections may play in human disease is unknown.^{22,48,94,96,110,129,146} The animal isolates are diverse and have DNA sequences that differ slightly from human *C. pneumoniae* isolates.¹²⁷ It

FIG. 194.2 Electron micrographs of (A) *Chlamydia trachomatis* and (B) *Chlamydia pneumoniae* inclusions demonstrating the morphology of the elementary body. The elementary bodies of *C. pneumoniae* have a pear shape because of a loose periplasmic membrane (arrows), unlike the typically round elementary bodies of *C. trachomatis* and *C. psittaci*.

has been hypothesized that human *C. pneumoniae* may be zoonotic in origin.^{127,129,135,137} Human isolates have been found to be relatively uniform.¹⁹ Currently no strain typing system has been developed for *C. pneumoniae*. The mode of transmission remains unclear but probably involves infected respiratory tract secretions. Acquisition of infection by droplet aerosol was described during a laboratory accident.⁸⁹ *C. pneumoniae* can remain viable on Formica countertops for 30 hours and can survive small-particle aerosolization.^{50,164} Spread of *C. pneumoniae* within families and enclosed populations such as military recruits and prisoners has been described. Outbreaks among these populations appear to becoming more frequent.^{49,102,105,178} In contrast, the proportion of community-acquired pneumonia associated with *C. pneumoniae* infection in adults has ranged from 0% to 19%, varying with the geographic location, the age group examined, and the diagnostic methods used.* Three studies published after 2010, from diverse geographic areas (Europe, Africa, and Thailand), that used rt-PCR found prevalence of *C. pneumoniae* infection ranging from 0% to 3.8%.^{43,99,104,160} This was compared with 11.4% in a Chinese study published in 2012 that only used MIF serology; 30% of the patients only had a single serum sample.¹⁶⁷

Studies of the role of *C. pneumoniae* in lower respiratory tract infections in pediatric populations have found evidence of infection in 0.3% to more than 44% (Table 194.3). Most of these studies relied entirely on serology for diagnosis. Early studies that relied on serology suggested that infection in children younger than 5 years was rare^{112,177}; however, in a study of Filipino children younger than 5 years with lower respiratory tract infection, nearly 10% had either acute or chronic antibody to *C. pneumoniae*.¹⁵² In Brooklyn, the proportion of lower respiratory tract infections associated with *C. pneumoniae*, as determined by culture, increased from 9% in children younger than 5 years to 19% in children and adolescents 5 to 16 years of age.³⁵

Studies that have used culture or PCR have found a poor correlation with serology, especially in children.^{21,46,57,58,83,111,113} Although 7% to 13% of children 6 months to 16 years of age enrolled in two multicenter pneumonia treatment studies were culture positive and 7% to 18% met the serologic criteria for acute infection with the MIF test, they were not the same patients.^{21,83} Only 1% to 3% of the culture-positive children met the serologic criteria, and approximately 70% were seronegative.

Prolonged culture positivity lasting several weeks to several years after acute infection has been reported.^{35,46,75} Asymptomatic nasopharyngeal carriage also occurs in 2% to 5% of adults and children.^{20,46,62,90,91,109} The role that asymptomatic carriage plays in the epidemiology of *C. pneumoniae* is not known, but possibly these persons could serve as a reservoir for spread of infection.

Clinical Manifestations

Most *C. pneumoniae* respiratory infections are mild or asymptomatic. Longitudinal serologic data obtained during an epidemic among military recruits in Finland suggest that only approximately 10% of infections result in clinically apparent pneumonia.^{102,105} Initial reports emphasized mild atypical pneumonia clinically resembling that associated with *Mycoplasma pneumoniae*.^{63,64,153,156} In several subsequent studies, however, pneumonia associated with *C. pneumoniae* was clinically indistinguishable from other pneumonias.^{21,83,85} Coinfection with other pathogens, especially *M. pneumoniae*, *Streptococcus pneumoniae*, and viruses, is frequent.^{21,83,85,165,169} In one multicenter pneumonia treatment study, 20% of the children with positive *C. pneumoniae* cultures were coinfecting with *M. pneumoniae*; they could not be distinguished from children who were infected with either organism alone.²¹ In these cases, *C. pneumoniae* may not be the primary cause of the pneumonia but might disrupt the normal clearance mechanisms and enable other pathogens to invade. This may have been the case in an outbreak of pneumonia and fatal pneumococcal meningitis among US Army trainees.⁴⁰ Six of 12 trainees with pneumonia were infected with *C. pneumoniae*, which suggested a simultaneous outbreak of both infections. *C. pneumoniae* has been associated with severe illness and even death, although the role of preexisting chronic conditions as contributing factors in many of these patients is difficult to assess. In some cases, however, *C. pneumoniae* clearly appears to be implicated as a serious pathogen, even in the absence of underlying disease. *C. pneumoniae* was isolated from the respiratory tract and the pleural fluid of a previously healthy adolescent boy with severe pneumonia complicated by respiratory tract failure and pleural effusions (Fig. 194.3).⁵

C. pneumoniae appeared to be responsible for 14% to 19% of episodes of acute chest syndrome in children with sickle cell disease.^{41,111,126,128} *C. pneumoniae* infection in these patients appeared to be associated with more severe hypoxia than was infection with *M. pneumoniae*.

C. pneumoniae may act as an inflammatory trigger for asthma. Several cases of culture-documented *C. pneumoniae* infection in patients with significant bronchospasm have been reported.^{70,75} Asthmatic bronchitis was diagnosed in one patient who was receiving systemic and inhaled steroids.⁷⁵ This patient did not improve until her chlamydial infection was treated. Hahn and associates⁷⁰ reported an association between serologic evidence of acute *C. pneumoniae* infection and wheezing in adults seen for lower respiratory tract illness. However, they were able to isolate the organism from only one of 365 patients. As part of a study in children, *C. pneumoniae* was isolated from 13 of 118 children (11%) 5 to 15 years of age who were evaluated initially for either new or acute exacerbations of asthma.⁴⁶ Treatment of the infection appeared to result in both clinical improvement and improvement in pulmonary function test scores. Only five of the children with confirmed infection had detectable IgG antibody to *C. pneumoniae*. One child who did not comply with his antibiotic therapy was culture positive on five occasions during a 3-month period. Anti-*C. pneumoniae* antibody as determined

*References 7, 21, 51, 77, 111, 114, 115, 117, 124, 127, 144, 152, 155, 169, 170, 172, 177, 179.

FIG. 194.3 Chest radiograph of a 19-year-old man with *Chlamydia pneumoniae* pneumonia demonstrating pleural effusion in the right lung. *C. pneumoniae* was isolated from the pleural fluid. (From Augenbraun MH, Roblin PM, Mandel LJ, et al. *Chlamydia pneumoniae* pneumonia with pleural effusion: diagnosis by culture. *Am J Med.* 1991;91:437-438.)

by MIF was never detected. Specific anti-*C. pneumoniae* IgE was, however, detected in 85.7% of the culture-positive asthmatic patients in contrast to 9% of the children with *C. pneumoniae* pneumonia who were not wheezing.⁴⁷ This finding suggests that the bronchial reactivity seen with *C. pneumoniae* infection may be IgE mediated. The potential prolonged, persistent *C. pneumoniae* infection may produce chronic inflammation and trigger bronchospasm in susceptible persons. *C. pneumoniae* has been demonstrated to induce in vitro ciliostasis in ciliated bronchial epithelial cells.^{157,161} Animal studies also suggest that steroids can reactivate *C. pneumoniae* lung infection in mice.¹¹⁹ In addition, immune-mediated phenomena, including erythema nodosum and iritis, have been described as complicating *C. pneumoniae* infection.^{163,165,175,177}

The role of *C. pneumoniae* in upper respiratory tract infections is not as well defined. *C. pneumoniae* has been isolated from the middle ear fluid of children and adults with otitis media.^{20,137-139} Block and colleagues²⁰ recovered *C. pneumoniae* from the middle ear fluid of eight children, 3 months to 14 years of age, with acute otitis media. *C. pneumoniae* was the sole pathogen isolated in two patients. Copathogens in the remaining six patients included β -lactamase-positive *Haemophilus influenzae* and *Moraxella catarrhalis*, along with penicillin-resistant and penicillin-sensitive *S. pneumoniae*. Five of the children who tested positive for *C. pneumoniae* responded favorably despite not being treated with antibiotics active against the organism, either a course of an oral β -lactam or single-dose intramuscular ceftriaxone. Symptoms suggestive of sinus involvement are not uncommon in patients with upper respiratory tract infection associated with *C. pneumoniae*, but only one case of isolation of the organism, from a 47-year-old man with sinusitis, has been reported.^{85,86} Cultrara and colleagues³⁹ examined nasopharyngeal swabs, ethmoid and maxillary sinus biopsy samples, and adenoids from 20 children, 3 to 16 years of age, with chronic sinusitis. *C. pneumoniae* was not isolated from any sinus tissue but was isolated from the nasopharyngeal swab and adenoid tissue of a 6-year-old. The results of this study suggest that *C. pneumoniae* does not play a significant role in chronic sinusitis in children.

Diagnosis

A specific laboratory diagnosis of *C. pneumoniae* infection can be made by isolation of the organism from nasopharyngeal or throat swabs, sputum, or pleural fluid, if present. The nasopharynx appears to be the

optimal site for isolation of the organism.²¹ *C. pneumoniae* grows readily in cell lines derived from respiratory tract tissue, specifically HEP-2 and HL cells.^{147,149} Culture with an initial inoculation and one passage can take 4 to 7 days.

Nasopharyngeal cultures can be obtained with Dacron-tipped, wire-shafted swabs. Each lot of swabs should be treated in a mock infection system to ensure that no inhibitory effects occur on either the viability of cells or recovery of chlamydiae. Specimens for culture should be placed in appropriate transport media, usually a sucrose phosphate buffer with antibiotics and fetal calf serum, and stored immediately at 4°C (39.2°F) for no longer than 24 hours. Viability decreases if specimens are held at room temperature. If the specimen cannot be processed within 24 hours, it should be frozen at -70°C (-94°F) until culture can be performed. After 72 hours of incubation, culture confirmation can be performed by staining with either a *C. pneumoniae* species-specific or a *Chlamydia* genus-specific (anti-LPS) fluorescein-conjugated monoclonal antibody.^{129,130,131,147,149} Unfortunately, no commercially produced *C. pneumoniae*-specific culture-confirmation reagents are available. If a genus-specific antibody is used, *C. pneumoniae* should be confirmed by differential staining with a specific *C. trachomatis* antibody; if that result is negative, the isolate is either *C. pneumoniae* or *C. psittaci*. If the patient has not had avian exposure, psittacosis would be highly unlikely.

The most common method still used by investigators for the diagnosis of *C. pneumoniae* infection is serologic testing. Assays available for detection of *C. pneumoniae*-specific antibodies include MIF tests, enzyme-linked immunosorbent assays (ELISAs), and EIAs, each of which exists in a variety of in-house and commercial versions.¹⁷¹ MIF is considered by the CDC to be the only currently acceptable serologic test, and therefore it is considered to be the reference standard for serodiagnosis, despite significant limitations.⁴² The recommendations proposed by the CDC⁴² in 2001 defined the criteria for serologic diagnosis of acute *C. pneumoniae* infection as a single IgM titer of 1:16 or greater or a fourfold increase in the IgG titer, as determined by MIF testing. The use of single IgG titers was discouraged. However, not only is the literature replete with studies that deviate widely from the proposed guidelines¹¹² but also several limitations exist that are inherent for serodiagnosis of *C. pneumoniae* infection, even when these guidelines are observed. The MIF assay has been repeatedly and conclusively demonstrated to be insensitive and have poor correlation with the detection of the organism by culture or PCR assay, particularly for children.^{58,112} Seventy percent of children 6 months to 16 years of age in two multicenter pneumonia treatment studies and 7 of 12 (58.3%) children 5 to 16 years of age with acute wheezing who had culture-documented infection had seronegative results by MIF test.^{21,46,83,84} Only 1% to 3% of culture-positive children in the former study and 25% in the latter met the serologic criteria for acute infection. Most of the children remained seronegative, even after 3 months of follow-up.⁴⁶

Background rates of seropositivity also can be high in some populations. Hyman and associates,^{91,92} as part of a study of asymptomatic *C. pneumoniae* infection in subjectively healthy adults in Brooklyn, found 81% to have IgG or IgM titers of 16 or higher. Seventeen percent had evidence of "acute infection" (i.e., IgG titer ≥ 512 , IgM titer ≥ 16 , or both). However, none of these persons was culture or PCR positive. Similar results were reported by Kern and associates¹⁰³ in healthy firefighters and policemen in Rhode Island. Some IgG antibody may result from a heterotypic response to other chlamydial species because cross-reactions with MOMP occur among the three species, as do cross-reactions caused by the genus LPS antigen. Moss and colleagues¹³⁵ reported that antibodies to *C. pneumoniae* and *C. psittaci* were found in as many as half of all chlamydial IgG-positive persons attending an STI clinic. This point is reinforced by the observation that studies from the early 1980s suggesting *C. trachomatis* as a cause of community-acquired pneumonia and pharyngitis in adults and children were probably detecting antibody to *C. pneumoniae* rather than *C. trachomatis*.^{59,105,106,108,142} or, in one outbreak in a boys school, *C. psittaci*.¹⁴⁰ Other organisms that have been reported as possibly causing cross-reactions on MIF are *Bartonella*^{121,123} and *Bordetella pertussis*.^{93,95} The latter could be significant because older children and adolescents with pertussis frequently have a chronic cough or severe bronchitis, which is a clinical feature often

ascribed to *C. pneumoniae*. Other studies have found significant homology between human and *C. pneumoniae* heat shock protein 60 (HSP-60) and *Escherichia coli* GroEL.^{136,138}

Moreover, the MIF test is not standardized, and reading of the slides has a large subjective component and requires an experienced microscopist. Littman and associates¹¹⁸ evaluated the interlaboratory reliability of the MIF test for measurement of *C. pneumoniae*-specific IgA and IgG titers for 392 serum samples, using reagents and antigens obtained from a common source. The investigators reported the exact agreement of IgA and IgG titers to be 55% and 38%, respectively, and the agreement within a twofold dilution to be 75% and 66%, respectively. EIAs may overcome some of the limitations of the MIF test by being objective and less technically complex. However, the CDC did not endorse any EIA, pending demonstration of adequate sensitivity and specificity in contrast to the MIF test. None of the currently available EIAs has FDA approval. Herrmann and colleagues⁸⁸ compared seven commercial EIAs or ELISAs (one of which was genus-specific) with four MIF assays for detection of specific IgG antibodies, using serum samples from 80 healthy subjects; they reported sensitivities and specificities ranging from 88% to 100% and from 42% to 100%, respectively. Similar results have been reported by others with the same assays in different populations, including children.^{111,120,139,170,171,173}

Multiple in-house NAAT methodologies (such as PCR) have been published, but the literature has been confounded by lack of standardization and validation. In 2000, a CDC workshop suggested a few assays that were considered to be validated enough to be used for research.⁴² The advantages of these NAAT or PCR assays are their sensitivity, decreased possibility of contamination, and ability to quantify DNA. More than a decade later, however, many of these tests turned out to be highly prone to false-positive results.⁴ Numerous in-house PCR-based tests still are performed, but these assays range from those that are well validated to those that are not validated at all. Although NAATs offer the promise of exquisite sensitivity, theoretically allowing detection of a single organism in a clinical sample, both false-negative and false-positive results can and do occur because of a large number of technical issues that were summarized recently.⁴ Currently, rt-PCR technology for the detection of *C. pneumoniae* should be used.¹⁵ rt-PCR offers significant advantages over conventional PCR in its rapidity, the ease with which it can be automated, the potential decreased risk for carryover contamination, and the potential provision of a quantitative result.

Until recently, there have been no commercially available NAAT assays. BioFire Technologies (formerly Idaho Technologies) developed a FilmArray assay for the detection of 17 viruses, which is FDA cleared.¹⁴³ The FilmArray system now includes assays on the same platform for some of the atypical agents of pneumonia, including *C. pneumoniae*, *M. pneumoniae*, and *B. pertussis*. This assay received FDA clearance in July 2012. The FilmArray system combines nucleic acid extraction, nested PCR, detection, and data analysis in a single-use pouch. However, data on the performance of this assay for detection of *C. pneumoniae* in clinical settings are limited. Most of the published studies that evaluated the performance of the BioFire FilmArray respiratory panel were limited to respiratory viruses or had very few patients with *C. pneumoniae* infection.^{3,33,38,143} Several other similar assays are being developed by other companies.³³

Treatment

Chlamydia spp. are susceptible to tetracyclines, macrolides, and quinolones.^{72,107} *C. pneumoniae*, like *C. psittaci*, is resistant to sulfonamides.^{72,107} To date, few published data have described the response of *C. pneumoniae* to antimicrobial therapy. Most of the treatment studies of pneumonia caused by *C. pneumoniae* published thus far have relied entirely on diagnosis by serology; consequently, microbiologic efficacy could not be assessed. Anecdotal reports have suggested that prolonged courses, up to 3 weeks, of either tetracyclines or erythromycin may be needed to eradicate *C. pneumoniae* from the nasopharynx of adults with influenza-like illness and pharyngitis.⁷⁵ The results of two pediatric multicenter pneumonia treatment studies found that 10-day courses of erythromycin and clarithromycin and 5 days of azithromycin suspension were equally efficacious; they eradicated the organism in 79% to 86% of children.^{21,83,85,148} Quinolones, including levofloxacin and

moxifloxacin, also have been demonstrated to have 70% to 80% efficacy in eradicating *C. pneumoniae* from adults with community-acquired pneumonia.^{81,82,73} Most patients improved clinically despite persistence of the organism. Persistence does not appear to be secondary to the development of antibiotic resistance because the maximum inhibitory concentrations of the isolates obtained after treatment did not change.^{72,73,82,84,107,148,150}

On the basis of these limited data, the following regimens for respiratory tract infection caused by *C. pneumoniae* can be suggested: in adults, doxycycline 100 mg twice daily for 14 to 21 days; tetracycline 250 mg four times daily for 14 to 21 days; azithromycin 1.5 g for 5 days; levofloxacin 500 mg/day orally or intravenously for 7 to 14 days; and moxifloxacin 400 mg/day orally for 10 days. For children, suggested regimens include erythromycin suspension 50 mg/kg per day for 10 to 14 days; clarithromycin suspension 15 mg/kg per day for 10 days; and azithromycin suspension 10 mg/kg on day 1 followed by 5 mg/kg per day once daily on days 2 to 5. Some patients may require retreatment.

Rickettsial and Ehrlichial Diseases

Paul M. Lantos • Ross McKinney Jr

The Rickettsiaceae are a family of organisms that share a fascinating history and common biology. The critical steps in the epidemiology were first characterized by Howard T. Ricketts in the early 20th century. He was doing fieldwork in the Bitterroot Valley in Montana and described how Rocky Mountain spotted fever (RMSF) was transmitted by the Rocky Mountain wood tick. Interestingly, before he did his work demonstrating tick-dependent transmission using guinea pigs, the fact that human transmission was through a tick vector had already been proved. In the *Transactions of the Chicago Pathological Society*, Dr. Ricketts reported¹⁵⁰:

At the time this work was done I had no knowledge of previous experiments which demonstrated the ability of the "wood tick" to transfer spotted fever. Recently I have had authoritative information that Dr. L. P. McCalla and Dr. H. A. Brereton, of Boise City, Idaho, transmitted the disease from man to man in two experiments. The tick was obtained "from the chest of a man very ill with spotted fever," and "applied to the arm of a man who had been in the hospital for two months and a half, and had lost both feet from gangrene due to freezing." On the eighth day the patient became ill and passed through a mild course of spotted fever, leaving a characteristic eruption. The experiment was repeated by placing the tick on a woman's leg, and she likewise was infected with spotted fever. Although these results received no publicity other than that given in reports to local societies, I take pleasure in according to Dr. McCalla and to his colleague, Dr. Brereton, the credit of having first shown that the tick may act as a carrier of spotted fever. Their experiments preceded by more than a year those of Dr. King and of myself, and they were performed with the full consent of the patients concerned.

The study was more fully described by Dr. McCalla in 1908.¹¹³

Sadly, funding for Dr. Ricketts' RMSF research dried up, and he moved to Mexico to investigate an outbreak of tabardillo, a Mexican typhus fever, which he suspected was similar in biology to RMSF. He identified lice as the vector for the disease, but in his attempt to isolate the causative organism, he contracted typhus and died. Shortly before his death, he learned that the state of Montana was ready to resume funding of his research on RMSF. (This is, of course, a cautionary tale to all academics with insecure funding.)

Rickettsiae are small coccobacilli in the class Alphaproteobacteria,⁶⁵ visible by light microscopy, that cause their disease intracellularly. The challenging nature of their physical identification was borne out by the fact that Howard Ricketts thought the cause of RMSF was a viral infection. The organism eventually named *Rickettsia rickettsii* was first described by Simeon Burt Wohlbach in 1916, although it took several years for his identification of a 0.2- to 0.5- μ m gram-negative organism to be confirmed.^{72,197} Rickettsiae cause disease by multiplying in the vascular endothelium, producing a generalized vasculitis involving mostly small blood vessels and symptoms that can involve nearly the entire body.

The human rickettsiae are in the family Rickettsiaceae, which is divided into two genera, *Rickettsia* and *Orientia*.²⁹ The rickettsiae are the more important pathogens and consist of the spotted fever group and the typhus group.¹⁶⁹ *Orientia* includes only one pathogen, *Orientia tsutsugamushi*, the cause of scrub typhus. The Anaplasmataceae family is closely related and is divided into two genera, *Anaplasma* and *Ehrlichia*.¹⁴⁷

All of the infections discussed in this chapter are transmitted by arthropod vectors. The spotted fever group of rickettsiae is predominantly

transmitted by ticks, although rickettsialpox is spread by mites. Scrub typhus is spread by human body lice as well as by ticks, and murine typhus is spread by fleas (Table 195.1).

Rickettsiae are important causes of human disease and have, in fact, played a profound role in human history.²⁰⁶ This chapter reviews the pediatric manifestations of diseases caused by the spotted fever and typhus groups of *Rickettsia*, *Ehrlichia*, and Anaplasmataceae.

SPOTTED FEVERS

The spotted fever group of the genus *Rickettsia* is composed of pathogens that are arthropod borne, mostly by ticks. The exception is rickettsialpox, caused by *Rickettsia akari*, which is a mite-borne infection. Disease produced by *R. rickettsii*, of which RMSF is the prototype, occurs throughout the Americas. There are a variety of other spotted fever illnesses seen around the world, most of which are less clinically severe. These diseases are distinguished by their geography and by variations in the causative organism, but they share their sensitivity to tetracyclines and their obligately intracellular life cycle.

Rocky Mountain Spotted Fever

Historical aspects. RMSF has an unusually fascinating history. It was originally recognized in the Bitterroot Valley of western Montana, nestled against the Idaho border. According to Howard Ricketts, the first description of "the so-called spotted fever of Idaho" was made by Edward E. Maxey of Boise City, Idaho, in 1899.¹⁵¹ The description of the illness, like many clinical characterizations of disease in the prelaboratory era, was surprisingly consistent with our view today, "an acute, endemic, non-contagious, but probably infectious, febrile disease, characterized clinically by a continuous moderately high fever, severe arthritic and muscular pains, and a profuse petechial or purpuric eruption in the skin, appearing first on the ankles, wrists, and forehead, but rapidly spreading to all parts of the body."¹⁵¹ The disease was soon recognized throughout the Rocky Mountain states. Whereas there were speculations that ticks were the vectors of RMSF, it was Ricketts who unequivocally proved the association through carefully performed experiments with a guinea pig model of disease. As noted earlier, he died before he was able to identify the causative organism of RMSF with certainty, a step performed by Simeon Burt Wohlbach in 1916. Wohlbach noted that the organism occurred in large numbers in the smooth muscle cells of arteries and veins. There were disputes between Wohlbach and researchers at the Rockefeller Institute in New York as to whether this new small organism was in fact the real pathogen. The dispute was sadly resolved when a laboratory technician working with RMSF at the Rockefeller Institute developed a fever, perhaps after a needle scratch, and died. The technician's blood was transported to Wohlbach's laboratory, where he inoculated guinea pigs and they became symptomatic with characteristic RMSF (in a guinea pig, fever, rash, and vasculitis). Wohlbach chose to name the organism after Howard Ricketts, whom he believed had, in fact, first seen the organism.

Another challenge was to grow the organism, then known as *Derma-centroxenus rickettsii*. It was originally thought that the organism could be grown only in cell cultures,¹⁹⁸ which led to confused debates about whether the organism was an intracellular bacterium or a virus. The answers came as Herald R. Cox discovered that rickettsiae could be grown in larger numbers in the yolk sacs of fertilized chicken eggs.³³

Many mysteries remain about certain elements in the natural history of RMSF. For example, the preantibiotic era mortality rate of RMSF in

TABLE 195.1 Classification, Primary Vector, and Reservoir Occurrence of Rickettsiae Known to Cause Disease in Humans

Antigenic Group	Disease	Species	Vector	Animal Reservoirs	Geographic Distribution
Anaplasma	Human granulocytic anaplasmosis	<i>Anaplasma phagocytophilum</i>	Tick	Deer, elk, small mammals, and rodents	Worldwide
Ehrlichia	Human monocytic ehrlichiosis	<i>Ehrlichia chaffeensis</i>	Tick	Deer, wild and domestic dogs, domestic ruminants, and rodents	Worldwide
	Ehrlichiosis	<i>E. muris</i>	Tick	Deer and rodents	Western United States, Russia, Japan
	Ehrlichiosis	<i>E. ewingii</i>	Tick	Deer, wild and domestic dogs, and rodents	North America
Neorickettsia	Sennetsu fever	<i>Neorickettsia sennetsu</i>	Trematode	Fish	Japan, Malaysia, possibly other parts of Asia
Scrub typhus	Scrub typhus	<i>Orientia tsutsugamushi</i>	Laval mite (chigger)	Rodents	Asia-Pacific region from maritime Russia and China to Indonesia and North Australia to Afghanistan
Spotted fever	Rickettsiosis	<i>Rickettsia aeschlimannii</i>	Tick	Unknown	South Africa, Morocco, Mediterranean littoral
	African tick bite fever	<i>R. africae</i>	Tick	Ruminants	Sub-Saharan Africa, West Indies
	Rickettsialpox	<i>R. akari</i>	Mite	House mice, wild rodents	Countries of the former Soviet Union, South Africa, Korea, Turkey, Balkan countries, North and South America
	Queensland tick typhus	<i>R. australis</i>	Tick	Rodents	Australia, Tasmania
	Mediterranean spotted fever or boutonneuse fever	<i>R. conorii</i> ^a	Tick	Dogs, rodents	Southern Europe, southern and western Asia, Africa, India
	Cat flea rickettsiosis	<i>R. felis</i>	Flea	Domestic cats, rodents, opossums	Europe, North and South America, Africa, Asia
	Far Eastern spotted fever	<i>R. heilongjiangensis</i>	Tick	Rodents	Far East of Russia, northern China, eastern Asia
	Aneruptive fever	<i>R. helvetica</i>	Tick	Rodents	Central and northern Europe, Asia
	Flinders Island spotted fever, Thai tick typhus	<i>R. honei</i>	Tick	Unknown	Australia, Thailand
	Japanese spotted fever	<i>R. japonica</i>	Tick	Rodents	Japan
	Australian spotted fever	<i>R. marmionii</i>	Tick	Rodents, reptiles	Australia
	Mediterranean spotted fever—like disease	<i>R. massiliae</i>	Tick	Unknown	France, Greece, Spain, Portugal, Switzerland, Sicily, central Africa, and Mali
	Maculatum infection	<i>R. parkeri</i>	Tick	Rodents	North and South America
	Rocky Mountain spotted fever, febre maculosa, São Paulo exanthematic typhus, Minas Gerais exanthematic typhus, Brazilian spotted fever	<i>R. rickettsii</i>	Tick	Rodents	North, Central, and South America
	North Asian tick typhus, Siberian tick typhus	<i>R. sibirica</i>	Tick	Rodents	Russia, China, Mongolia
	Lymphangitis-associated rickettsiosis	<i>R. sibirica mongolotimonae</i>	Tick	Rodents	Southern France, Portugal, China, sub-Saharan Africa
	Tick-borne lymphadenopathy (TIBOLA), Dermacentor-borne necrosis and lymphadenopathy (DEBONEL)	<i>R. slovaca</i>	Tick	Lagomorphs, rodents	Southern and eastern Europe, Asia
Typhus fever	Epidemic typhus, sylvatic typhus	<i>R. prowazekii</i>	Human body louse, flying squirrel ectoparasites, <i>Amblyomma</i> ticks	Humans, flying squirrels	Central Africa; Asia; Central, North, and South America
	Murine typhus	<i>R. typhi</i>	Flea	Rodents	Tropical and subtropical areas worldwide

^aIncludes four different subspecies that can be distinguished serologically and by polymerase chain reaction assay and respectively are the etiologic agents of boutonneuse fever and Mediterranean tick fever in southern Europe and Africa (*R. conorii* subsp. *conorii*), Indian tick typhus in south Asia (*R. conorii* subsp. *indica*), Israeli tick typhus in southern Europe and Middle East (*R. conorii* subsp. *israelensis*), and Astrakhan spotted fever in the North Caspian region of Russia (*R. conorii* subsp. *caspiiae*). From Ermeeva ME, Dasch GA. Rickettsial (spotted & typhus fevers) & related infections (anaplasmosis & ehrlichiosis). In: CDC Yellow Book Online. <http://www.cdc.gov/travel/yellowbook/2012/chapter-3-infectious-diseases-related-to-travel/rickettsial-spotted-and-typhus-fevers-and-related-infections-anaplasmosis-and-ehrlichiosis.htm>.

Idaho was 5% to 7%, whereas in the Bitterroot Valley of Montana, it was 70%.⁸⁵ The molecular basis for this difference in virulence remains unclear even today.²⁹ The epidemiology of RMSF has evolved during the 20th century from being a disease predominantly recognized in the northern Rocky Mountains to a disease most commonly found in a band of contiguous states from Oklahoma to the Carolinas (Fig. 195.1). North Carolina, Tennessee, Arkansas, Missouri, and Oklahoma account for 60% of the reported RMSF cases in the United States.¹⁶³ The incidence

of RMSF has been generally rising, whereas the case-fatality rate has been falling (Fig. 195.2). In 2008, there were roughly 2500 cases of RMSF in the United States, the largest number on record.¹⁶³ In 2008–12, passive surveillance reported 8.9 cases of RMSF per million persons in the United States.

For surveillance purposes the CDC has replaced RMSF with the label “spotted fever group rickettsia” because of the similarity between the clinical syndromes produced by *R. rickettsii*, *Rickettsia parkeri*, and

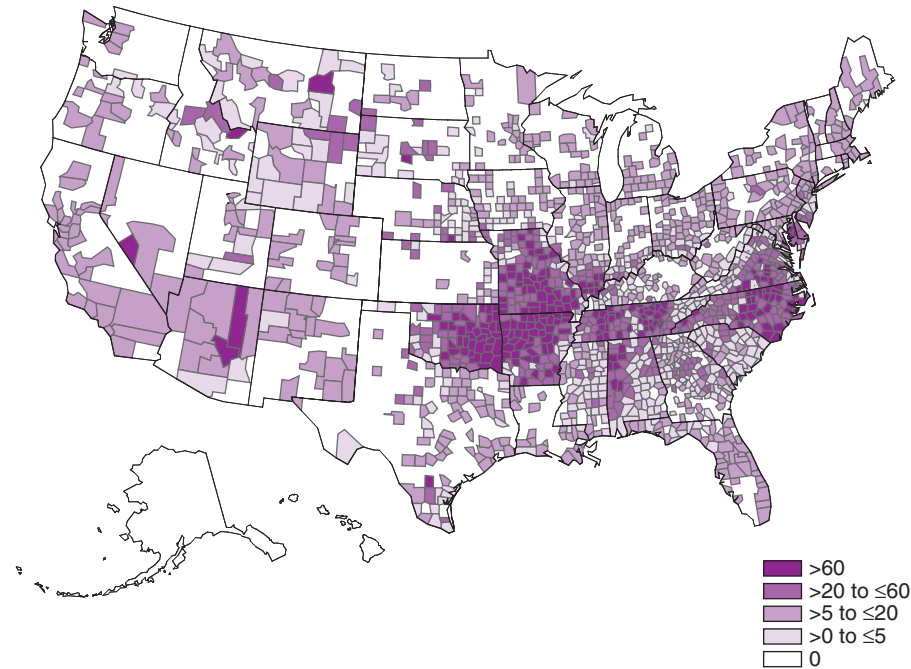

FIG. 195.1 Reported incidence rate of spotted fever rickettsiosis, by county—United States, 2000–13. As reported through national surveillance, per 1 million persons per year. Cases are reported by county of residence, which is not always where the infection was acquired. Includes Rocky Mountain spotted fever (RMSF) and other spotted fever group rickettsioses. In 2010, the name of the reporting category changed from RMSF to spotted fever rickettsiosis. (From Biggs HM, Behraves CB, Bradley KK, et al. Diagnosis and management of tickborne rickettsial diseases: Rocky Mountain spotted fever and other spotted fever group rickettsioses, ehrlichioses, and anaplasmosis—United States. *MMWR Recomm Rep.* 2016;65[2]:1–44.)

FIG. 195.2 Rocky Mountain spotted fever incidence and case fatality, 1920–2010. (From Centers for Disease Control and Prevention. Statistics and epidemiology: annual cases of RMSF in the United States. <http://www.cdc.gov/rmsf/stats/>.)

Rickettsia species 364D.¹² For the purposes of this chapter, we will use the traditional label of Rocky Mountain spotted fever, but it should be recognized there is some overlap with the other spotted fever group organisms.

Etiology, morphology, growth, and metabolism. *R. rickettsii*, the etiologic agent of RMSF, is a small, nonmotile, pleomorphic, weakly gram-negative coccobacillus measuring 0.3 to 0.5 μm in diameter and 0.3 to 4 μm in length. The cell wall and cytoplasmic membrane are fairly typical for gram-negative bacteria. Rickettsiae must penetrate into living cells to grow and multiply (i.e., they are obligately intracellular). They are grown most readily in the yolk sacs of embryonated eggs; but under special conditions, they also grow well in certain tissue culture cells. When inside a cell, rickettsial cells multiply by transverse binary fission.⁷⁵ The organisms lack the intrinsic ability to metabolize carbohydrates and amino acid substrates and derive energy from host adenosine triphosphate (ATP).²⁹

Rickettsiae take on a characteristic red color when stained with Gimenez stain. *R. rickettsii* possess a soluble antigenic moiety that is shared with antigenic variants in the spotted fever group and rickettsialpox.

Epidemiology and transmission. Because *R. rickettsii* is transmitted to people through adult tick vectors, understanding of tick ecology explains much of the epidemiology of RMSF. The vectors for RMSF are *Dermacentor variabilis* (the American dog tick) in the eastern and central United States, *Dermacentor andersoni* (the Rocky Mountain wood tick) in the Rocky Mountain states and West, and *Rhipicephalus sanguineus* (the brown dog tick) in eastern Arizona.¹⁶³ These ticks prefer woodlands where small rodents share habitats with large domestic and wild animals.²³ RMSF is most common in spring and summer months when ticks are most active.

Regionally, RMSF is concentrated. Fifty-six percent of cases come from five states (North Carolina, South Carolina, Tennessee, Oklahoma, and Arkansas). However, it is widely distributed in North America, and cases have been reported from all 48 contiguous United States.⁴³ It tends to occur in hyperendemic foci, and there are reports of family clusters of disease.⁵¹ *R. rickettsii* infection occurs throughout Central and South America via several different tick species; there are a variety of regional names for the infection, such as Tobia fever (Colombia) and São Paulo fever (Brazil).

The life cycle of *Dermacentor andersoni* ticks requires roughly 2 years. In the spring and early summer, adult ticks seek out hosts for a blood meal. Ticks that attach feed for 7 to 9 days, then mate. The engorged females drop off their hosts, laying 5000 to 7000 eggs each. After 35 days, the eggs hatch and the larvae seek out small mammals to which to attach. After 2 to 6 days of feeding, the larvae drop off, mature into nymphs, and become inactive for the winter. In the spring, the nymphs attach to small mammals, feed for 7 days, drop off, hide, and mature into adults. They generally hide for the duration of the summer, fall, and winter and in the spring seek out their adult blood meal.²³

D. variabilis is similar to the Rocky Mountain wood tick but adapted to the climate of the central and eastern United States. The larvae and nymphs have a narrower host range and show a preference for meadow and white-footed mice. Dogs are the primary hosts for the adult ticks, but the adult ticks are willing to bite a wide range of large mammals, including humans, who are thus incidental victims. Larvae are most active in the early spring (March and April), then become active again in the late summer (August and September) if they did not successfully feed in the spring. Nymphs are also active in spring and late summer, with the spring nymphs having overwintered and the late summer nymphs a product of spring larvae. Adults also most actively seek blood meals from April to September, although they can become active in any month if the weather is warm enough.²³

Rickettsiae multiply in ticks and small mammals. The organisms are found in the salivary gland of the ticks, and during a blood meal the organisms are activated and become more pathogenic. They are ultimately injected into the host by the tick during the course of the blood meal, although ticks can also transmit if they are squeezed during the process of tick removal.²⁹ Rickettsiae can be passed from one generation of tick to the next transovarially and can persist from hatching into the adult tick. This is particularly impressive because adult ticks can wait up to 4

years for a blood meal. However, infected ticks seem to have a biologic disadvantage, and relatively few *R. rickettsii*-infected larvae ultimately mature into adults.⁴⁹ The organisms are found in the salivary glands and the gastrointestinal tract of the ticks. Interestingly, RMSF is also a sexually transmitted disease; it can be spread from infected male ticks to uninfected females through infected spermatozoa.^{76,132}

Although it is uncommon, RMSF can be spread through aerosolization in the laboratory, so care should be taken (a biosafety level 3 facility is required). In addition, there have been uncommon transmissions by transfusion¹⁹¹ and needlestick accidents.¹⁵⁶

Seroprevalence studies have demonstrated that subclinical disease may be more common than symptomatic, although it is difficult to know whether the results reflect antibodies to rickettsiae other than *R. rickettsii* or perhaps cross-reactive antigens from other organisms.¹⁹⁵ A large seroprevalence survey of children at sites in the southeastern United States found *R. rickettsii* seropositivity rates that varied from 3.5% in Louisville, Kentucky, to 21.9% in Little Rock, Arkansas. These are rates that seem high relative to the incidence of clinical RMSF. Also noteworthy was the large jump in overall seroprevalence from the 1- to 6-year-old age group (4.2%) to the 7- to 12-year-olds (13.9%), suggesting a high rate of exposure in early school-aged children.¹¹²

Perhaps because *R. rickettsii* is biologically disadvantageous for ticks, it is relatively uncommon even in highly endemic areas. The tick prevalence of *R. rickettsii* infection is less than one RMSF infection per 1000 ticks, whereas many ticks have nonpathogenic rickettsiae like *Rickettsia montana* or *Rickettsia rhipicephali*.¹⁸⁰ This low prevalence is one of the primary reasons that there is no role for doxycycline prophylaxis after removal of an engorged tick.

Pathogenesis. Vasculitis is the fundamental disease process in RMSF. Rickettsiae infect the endothelial cells lining blood vessels, particularly of small and medium-sized blood vessels, and the resultant cellular damage creates vascular lesions that can involve almost the entire vascular bed. The process begins when the tick bites an individual and begins its blood meal. Rickettsiae are introduced from the salivary glands of the tick, and the infectious cycle begins.

At a cellular level, rickettsiae are internalized by endocytosis into vacuoles. They are initially enclosed in a vacuolar membrane but are able to degrade the membrane and escape into the cytosol. Rickettsiae are obligate intracellular pathogens, and they require access to the cytoplasm to grow. They lack the ability to metabolize carbohydrates and amino acids and thus obtain their energy from host ATP molecules.²⁹ When in the cytoplasm, the organisms replicate by binary fission. They recruit host cell actin molecules, and they use the actin to spread from cell to cell, transported through cell membranes without producing damage. They spread rapidly among the endothelial cells lining the vascular and lymphatic systems. As the cells become injured by the rickettsiae, they lose their attachment to adjacent cells, and the smooth vascular surface becomes increasingly rough and leaky.

The immune response to *R. rickettsia* involves perivascular lymphocytic infiltrates. As the endothelial cells fail, small leaks in the capillary bed produce increased vascular permeability, microhemorrhages, localized edema, and local inflammation. With time, the problem becomes more generalized, involving a wide variety of organs, including the skin, brain, lungs, kidneys, and liver. Eventually the combination of leakage, edema, and inflammation can produce organ failure. On pathologic examination in affected patients, inflammation can be seen in the affected tissues.

Clearance of *R. rickettsii* is predominantly by cellular immunity, including cytotoxic T lymphocytes and interferon- γ . The immune response lyses infected cells, an action that may be the primary means by which rickettsial infection causes cell injury.¹⁸⁰ A broad range of antibodies are produced against *R. rickettsii*, and these antibodies appear to be the host's primary defense against reinfection. Although it is not absolutely certain, it is generally believed that people are not infected by *R. rickettsii* more than once.

The laboratory hallmarks of RMSF are also a product of this diffuse vascular injury, with often profound thrombocytopenia and mild to moderate hyponatremia. The thrombocytopenia is a result of platelet consumption along damaged vascular surfaces; the hyponatremia is probably a combination of shifting of electrolytes from the intracellular to the extracellular space, loss of sodium through excretion, exchange

of sodium for potassium at the cellular level, and the syndrome of inappropriate antidiuretic hormone secretion.⁸⁹

The extent of disease is dependent on several factors in addition to the timing of treatment initiation. For example, there is the regional variation noted earlier (Montana vs. Idaho). The inoculum size is almost certainly important and may relate to the duration of tick attachment. Most of the time, *R. rickettsii* in tick salivary glands are in a dormant, noncontagious state. During the blood meal, the rickettsiae become active and virulent, a process that may take as long as 4 to 6 hours. As a result, that duration is thought to be the necessary length of attachment for transmission to occur. Host factors that make RMSF potentially more severe include glucose-6-phosphate dehydrogenase (G6PD) deficiency (a sex-linked condition found in 12% of African American males), age (adults are at higher risk for severe disease), and gender (males more than females).¹⁸⁰

Clinical manifestations. The classic manifestations of RMSF are fever, headache, myalgias, severe malaise, and rash. The illness is seldom subtle, and most children infected with *R. rickettsii* appear quite ill. Temperatures in the range of 40°C (104°F) are typical. In the early stages, rash may not be present or may be only pale, erythematous macules. In dark-skinned patients, the early rash may not be apparent. As the illness progresses, the fever persists, the degree of malaise becomes complete prostration, and the rash evolves from macules to petechiae. Eventually, the child can become hypotensive and obtunded and may die if not appropriately treated.

RMSF is transmitted by tick bite, but surprisingly only half of patients can recall being bitten by a tick.²¹ This probably reflects the facts that ticks are stealthy and generally obtain their blood meal efficiently, without pain. They may attach in areas that are not easily seen. The consequence for physicians is that the historical review should focus not only on tick bites but also on behaviors that put someone at risk for tick exposure. These behaviors include walking in woods or high grass in the spring or summer or during a sustained warm spell. In terms of RMSF, the degree of regional incidence of *R. rickettsii* infection should also be considered; the southeastern and south-central United States have the highest incidence.

The incubation period for RMSF after the tick bite is 48 hours to 14 days, with a median of 4 days.^{21,29} The first symptoms are usually fever, headache, myalgias, and malaise. These are obviously nonspecific findings, making the diagnosis of RMSF difficult. Fever is virtually a *sine qua non*, occurring in 98% of pediatric RMSF cases.²¹ Profound malaise is also present from early in the illness, marking RMSF as more than the typical nonspecific virus infection. Sixty percent of children develop a headache, which is often severe. Lumbar punctures typically have a mild leukocytosis, with a median of 25 cells/mm³.²¹

Rash is not reliably present in the early stages of disease, unfortunately. The rash typically appears in the second to fourth day of illness, which is generally after patients have first sought medical care.²⁸ Eventually 90% or more of children have rash. The early rash begins as faint macules, often on the arms and lower legs. At this stage, the lesions still blanch on pressure. Petechiae evolve during several days. Classically the rash evolves from the periphery toward the trunk and involves the palms and soles. However, neither the centripetal nature nor palm and sole involvement is a definitive or reliable finding. Generalized petechiae are seen around the fifth or sixth day of illness, at which point patients are severely ill. They are likely to have organ system dysfunction, and recovery will be slow even with treatment.²⁸

Other common symptoms are myalgia (45% in the Buckingham series),²¹ abdominal pain that can mimic appendicitis (36%), diarrhea (34%), conjunctival injection (33%), altered mental status (33%), lymphadenopathy (29%), and peripheral edema (25%). Less common findings include hepatomegaly, photophobia, seizures, meningismus, splenomegaly, periorbital edema, and coma. Of these symptoms, the conjunctival injection and peripheral edema are most likely to point in the direction of RMSF, although both usually occur in patients who already have extensive rash.

The laboratory findings are also only moderately helpful. As noted in the section on diagnosis, the only true acute diagnostic test is biopsy of petechial or macular lesions and demonstration of the organism by immunohistochemical staining or polymerase chain reaction (PCR)

testing. Antibody tests have almost no utility acutely because the immunofluorescent antibody (IFA) assay titers will not rise into a diagnostic range until 10 days or more into the illness, days after treatment should have been started. The two most useful laboratory findings are thrombocytopenia and hyponatremia. Sixty percent of children have a platelet count below 150,000 cells/mm³ at their initial presentation, and the median platelet count is 128,000 cells/mm³. In regard to serum sodium, 52% have sodium concentrations below 135 mEq/L, with a median concentration of 133 mEq/L. Other laboratory values that can be abnormal include hepatic enzymes (alanine aminotransferase, aspartate aminotransferase), serum bilirubin, hemoglobin, cerebrospinal fluid cell count, glucose, and protein.

Some patients with RMSF have focal cardiac disease, in particular myocarditis, and rare patients have evidence of pneumonia.

Even with treatment, RMSF can leave patients with residual neurologic damage, as described later in the prognosis section. Conditions associated with more severe RMSF, in addition to delayed treatment, include G6PD deficiency and early treatment with sulfa drugs.

Diagnosis. Because the early manifestations of *R. rickettsii* infection are nonspecific, the challenge is to diagnose RMSF effectively and to avoid overtreating a multitude of children. In the right season (summer) in an endemic region, this can be a significant problem. If an error is made, it should be in overtreatment of patients in whom infection is suspected, given the relative risks of undertreatment of RMSF versus the potential for unnecessary exposure to doxycycline.

For confirmation of a diagnosis of *R. rickettsii* infection, the most widely used test is the indirect IFA assay. The sensitivity of this assay is inadequate to be useful in the first 10 to 12 days of illness. There is essentially no value in a negative test result; it does not rule out RMSF and should not be used for that purpose. The value of IFA assay comes to confirm whether an illness was RMSF *ex post facto*. The test is 94% sensitive by 14 to 21 days.⁸⁸ The diagnosis requires a fourfold rise in titer between acute and convalescent sera. A “probable” diagnosis is generally made on the basis of a single convalescent IFA titer of 1:64 or greater.

To make a diagnosis of RMSF more acutely, if a patient has a rash, a skin biopsy can be performed to sample petechial lesions. The lesion can be sent for either immunohistochemical staining or PCR testing, depending on availability. Immunohistochemical staining of biopsy material has been found to be 100% specific and 70% sensitive.¹⁸¹ It is most useful either before or very early in treatment. PCR is less established as a diagnostic method but can be performed on either tissue or blood.

The other important but nonspecific diagnostic clues pointing toward RMSF are thrombocytopenia, hyponatremia, and the rash. One case series found the average platelet count at presentation to be 128,000 cells/mm³; 41% had fewer than 100,000 platelets at initial presentation.²¹ In terms of sodium, the median sodium concentration at presentation was 133 mEq/L, and 52% of children had a serum sodium concentration below 135 mEq/L. The rash, when present, is an important clue, but the absence of rash does not exclude RMSF. As noted before, the rash begins as faint macules, which become petechial as the disease progresses. They may be found on the palms and soles, but rashes in those locations are seen in only two-thirds of children.²¹

Differential diagnosis. Perhaps the greatest challenge to RMSF is making a clinical diagnosis in time for effective treatment. The characteristics that define early RMSF are fairly nonspecific: fever, headache, some photophobia, and severe malaise. The first critical clue is whether the patient has been in an endemic area, although RMSF has occurred in all of the lower 48 states, and whether the season is right (spring, summer, or a recent warm spell). A rash usually appears somewhere between the third and fifth day and can be a helpful clue, but roughly 10% of patients with confirmed RMSF never have a rash. Because of the lack of specificity to the symptoms, clinicians must begin with a high level of suspicion. Enteroviral infections (echovirus, coxsackievirus) appear similar to RMSF, have the same summer seasonality, and can produce a similar rash. In endemic regions, the practical reality is that quite a few enteroviral infections are “cured” with doxycycline.

A more problematic overlap is with *Neisseria meningitidis*. The early symptoms of meningococcemia are again similar to RMSF, with fever, headache, and malaise. Laboratory findings may also be similar, with

thrombocytopenia and a leukocyte count that reflects a left shift. Because neither RMSF nor meningococcemia can be quickly confirmed, and because both require a rapid initiation of treatment, it is reasonable and appropriate to begin both doxycycline and penicillin (or some other appropriate β -lactam or cephalosporin) until the situation can be sorted out (primarily by blood culture).

The full differential diagnosis for RMSF includes enteroviral infections, adenoviral infections, meningococcemia, influenza, gram-negative bacterial sepsis, toxic shock syndrome, measles, rubella, secondary syphilis, leptospirosis, typhoid fever, disseminated gonococcal infection, immune thrombocytopenic purpura, thrombotic thrombocytopenic purpura, immune complex vasculitis (e.g., systemic lupus erythematosus), infectious mononucleosis, hypersensitivity reaction to drugs, murine typhus, rickettsialpox, recrudescent typhus, and sylvatic *Rickettsia prowazekii* infection that is enzootic in flying squirrels.¹⁸⁰

During the summer in endemic regions, it is fairly common practice to see patients early in the course of a febrile illness. In the first 2 days of fever, practitioners often obtain screening laboratory tests (a complete blood count and chemistry) and, if the patient does not have severe malaise, opt to watch. If the fever persists into the third day, if the screening laboratory test results appear suggestive, or if the patient appears to be more ill than is usually the case with a viral illness, treatment with doxycycline is initiated. The worst outcomes with RMSF occur when a physician dogmatically holds to a preliminary diagnosis in the face of persisting illness, often because of the absence of a rash or laboratory test result pointing toward RMSF.

Treatment. RMSF is an easily treatable disease with a good prognosis if treatment is begun suitably early. However, therapeutic failures occur every summer because the diagnosis is not considered. The symptoms can mimic other diseases (e.g., enterovirus infection, meningococcemia, infectious mononucleosis, appendicitis, pharyngitis), prompting inappropriate treatment decisions. If doxycycline is initiated within the first 5 days of fever, the prognosis is excellent. The problem is deciding which patients to treat, which to observe. Even in areas where RMSF is endemic, 60% to 75% of patients with RMSF are given an alternative diagnosis at their first clinical visit. The probabilities of morbidity and mortality escalate rapidly with each day of treatment delay.

The other important challenge to treating RMSF is the need to begin treatment before the standard diagnostic test results become definitively positive. At the onset of fever, antibody titers against *R. rickettsii* will almost always be negative. In most cases, the IFA test result becomes positive between 7 and 10 days, and by 14 to 21 days, IFA titers are 94% sensitive. However, during the first week, when treatment needs to be initiated, antibody titers will be negative. Even defining who is at risk can be difficult. Because ticks are very good at their profession (blood sucking), in only 50% of cases do patients report a time-appropriate tick exposure.²¹

Doxycycline is the primary antibiotic used to treat RMSF. Historically, chloramphenicol was demonstrated to be equally effective, and it remains the only documented alternative treatment, but its side-effect profile, particularly in causing aplastic anemia, has made oral chloramphenicol unavailable in the United States. Doxycycline is dosed at 2.2 mg/kg per dose every 12 hours (maximum, 100 mg every 12 hours) for the duration of fever and an additional 3 days (at least 5 days, and typically 7 to 10 days). After the patient is improving, relapse is highly unlikely, and there is no chronic form of *R. rickettsii* infection. Doxycycline may be given intravenously or orally, depending on the degree of illness. Whereas tetracyclines have been associated with dental staining, doxycycline does not pose a significant risk (particularly in comparison to untreated RMSF).

Severe RMSF can require hospitalization and, at times, advanced life support: intravenous fluids, pressors, and assisted ventilation. In its severe form, RMSF includes a profound vasculitis that can mimic disseminated intravascular coagulopathy, with thrombocytopenia, generalized petechiae, hemorrhages, and shock. In many ways, it clinically resembles meningococcemia.

Whereas some children with RMSF are empirically treated with antibiotics other than doxycycline during the early phases of management, given the already noted similarity to meningococcemia, most of those antibiotics will have no effect on the course of RMSF. The one exception

is sulfa drugs, including trimethoprim-sulfamethoxazole, which can make RMSF more severe. The mechanism for this observation is still unclear.²⁸

Prognosis. The mortality rate in the modern era for untreated RMSF is 20%; for treated patients, it is roughly 5%.²⁸ Interestingly, in the preantibiotic era, the mortality rate for RMSF was highly variable. For example, RMSF in the Bitterroot Valley of Montana had a mortality rate of 75%, whereas in the Snake River Valley in southern Idaho it was 3%.³ The reasons for differential rates like these have never been explained.²⁹ Most of the current mortality is in patients with delayed initiation of doxycycline. For patients treated with doxycycline in the first 5 days of symptoms, the prognosis is excellent.

In children who have had severe RMSF, there is a significant rate of residual problems. In one series, 13 of 89 surviving children were discharged from the hospital with neurologic deficits, including speech and swallowing dysfunction, global encephalopathy, ataxia or gait disturbances, and cortical blindness.²¹ Many of the children with long-term follow-up continued to have neurologic problems. Two of the 89 children had loss of digits due to autoamputation.

Prevention. The most effective measures for control of RMSF are personal steps to avoid ticks. Wearing pants tucked into boots or socks is not a fashion statement, but it can be useful in tick avoidance. Permethrin-based insect repellants can be effective, although they should be applied to clothes rather than directly on skin (a caution for which users will be grateful after smelling permethrin-based repellants). Insect repellants containing 20% to 50% DEET applied to skin may have some effect, although they are probably more effective in deterring mosquitoes than ticks. Adults should perform regular tick inspections on themselves and on children for whom they are responsible because ticks require 4 to 6 hours of attachment to transmit *R. rickettsii*. Ticks are fond of high grasses, brushy areas, and mixed forests, so care should be taken to stay in the center of well-trodden trails. Pets can be protected with medications or flea and tick collars.¹³⁴

Patients should be taught the art of removing ticks from skin. There are many old wives' tales about how to remove ticks: touching their backs with an extinguished match, applying clear nail polish to suffocate them, applying petroleum jelly. Given the effectiveness of these strategies, the surprise is that there are any old wives left to tell tales. To remove a tick, use tweezers, grasp the tick's head as close to the skin as possible, and twist out. The area should be scrubbed with soap or alcohol because any residual tick spit or fecal material has the potential to be infectious and to contaminate the bite wound. Incinerating a tick after removal is, however, perfectly appropriate, as is the more usual approach of flushing it into the sewer system.

Whereas vaccines against RMSF were in use for many years, they were probably marginally effective, if at all, and are no longer available.

Mediterranean Spotted Fever

Overview. Mediterranean spotted fever (MSF) is a tick-borne infection caused by *Rickettsia conorii*. The disease was first described by Conor and Bruch in 1910,³² and the name "Mediterranean spotted fever" was adopted in 1932. In the Mediterranean region, this infection is also known as boutonneuse fever and Marseilles fever. Whereas the infection has been recognized for a century, until recently it was regarded as a benign disease. In 1982 the first case report of fatal MSF was published.¹⁴² Its potential lethality has been demonstrated in numerous other studies, including one in which 32.3% of hospitalized patients died.³⁸ It is now regarded as comparable to RMSF in its potential for mortality.

Epidemiology. *R. conorii* infection occurs across a wide geographic swath that includes not only the Mediterranean region but also parts of central and southern Africa, the Middle East, and central and south Asia. Locale-specific names given to this infection include Astrakhan spotted fever, Kenya tick bite fever, African tick typhus, India tick typhus, and Israeli spotted fever. The geographic diversity of MSF is matched by its genetic diversity; there are numerous regional subspecies of *R. conorii* capable of causing human disease.²⁰⁵ The only known vector is the brown dog tick, *Rhipicephalus sanguineus*. This tick is also the only known reservoir for *R. conorii*.

MSF occurs in all age groups of both sexes. The epidemiologic pattern is determined by the activity of the tick; consequently, a consistent

seasonal peak occurs from June to October. The incidence of the disease appears to rise and fall periodically. The most recent decades have seen an increase in cases in a number of countries, including Portugal, Italy, France, Spain, Bulgaria, and Algeria.¹⁵⁴

Clinical manifestations. The infecting bite is unnoticed in most cases. Conjunctival inoculation occurs occasionally. The incubation period ranges from 6 to 10 days. The primary lesion, tache noire (black spot), described and named by Pieri in the 1920s, develops at the site of the tick bite, is not painful, and is rarely pruritic.¹⁸³ It occurs most often on the head in children and on the legs in adults. The lesion develops central necrosis, then an eschar, and regional lymph nodes enlarge. The initial lesion heals slowly and resolves after 10 to 20 days without scarring, although residual pigmentation can persist indefinitely.

Tache noire is highly characteristic, but the lesion is identified in only 30% to 90% of patients. The occasional patient has multiple lesions. Formation of the lesion requires a substance secreted by the tick and another of rickettsial origin; it is not reproduced by a separate bite of an uninfected tick or by experimental inoculation of *R. conorii*. An inflammatory infiltrate, predominantly mononuclear, accumulates at the tache noire site, suggesting the importance of T cell-mediated immunity in local host defense.

The onset of disease usually is abrupt, with malaise and fever that reaches temperatures of 39°C to 40°C (102.2°F–104°F) within the first 2 or 3 days. The fever continues for 6 to 12 days, but antibiotics can shorten the febrile period. Severe and unremitting headache is a typical feature of the disease in adults.⁵ On the other hand, headache occurs in less than one third of pediatric patients.³¹ Arthralgia and myalgia, especially of the leg muscles, are prominent features in adults; in children, they are rarely of sufficient severity to restrict mobility.

By the third to fifth day of fever nearly all patients develop a maculopapular exanthem. Lesions first appear on the extremities, spreading within a day or so to the trunk, neck, face, buttocks, palms, and soles. The initial lesions are macular, pink, and irregularly defined but within hours become maculopapular. The rash can be intensely pruritic. Lesions generally measure 1 to 4 mm in diameter. The rash persists for 10 to 20 days after the illness has otherwise resolved. Atypical cutaneous manifestations include petechiae, purpura, or papulovesicular lesions.^{31,57}

The cutaneous manifestations of MSF are caused by infection of the vascular structures of the dermis. Ricketsemia during the incubation period probably seeds the endothelial cells of the capillaries, arterioles, and venules. The vasculitis produced is much like that seen in RMSF. It gradually disappears during convalescence, and as the maculopapules fade, a brown discoloration of the skin may be noticed.

Cardiovascular and respiratory changes are transient and nonspecific. Bradycardia is the most consistent finding, but other dysrhythmias can occur. More seriously ill patients have developed pericarditis, heart failure, and myocarditis. The most important vascular complication is phlebitis of the lower extremities. Deep vein thrombosis is a recognized complication, particularly among pregnant patients. Other important complications include pneumonitis, pleuritis, pleuropericarditis, and the adult respiratory distress syndrome.

In addition to the headache that is characteristic of rickettsial illnesses, varying degrees of impaired consciousness can occur. Rarely, stupor, delirium, convulsions, and transient hypoacusis may be noted. Rickettsial encephalitis may be followed by long-term neurologic sequelae.

Renal function is not altered in most cases, although nephritis with acute renal failure has occurred occasionally. The liver is palpable in one-third of patients, and the spleen may be enlarged in 20% of children. Tests of hepatic function reveal an increase in serum transaminase levels in one-fourth to one-half of pediatric cases. Alkaline phosphatase levels are elevated in one-third of patients. Liver pathology reveals foci of hepatocellular necrosis and a predominantly mononuclear reaction to the necrosis at sites of infection by *R. conorii*. The lesions differ from true granulomas in that they are not aggregates of epithelioid macrophages.¹⁸⁴

A variety of other systemic symptoms can occur. Photophobia and bilateral conjunctivitis have been reported. Severe unilateral conjunctivitis suggests that transmission of the disease occurs by the conjunctival route. Uveitis, choroiditis, retinal artery occlusion, and neuroretinitis are uncommon ocular disturbances.^{2,41}

Hematologic abnormalities include isolated cases of autoimmune anemia and mixed cryoglobulinemia associated with MSF. Some studies report a high incidence of hypoproteinemia. Immune complex-mediated vasculitis associated with MSF has been described.³⁶

On occasion, MSF can have a malignant, rapidly fatal course, even in previously healthy children. The illness is consistent with a widespread vasculitis characterized by irreversible shock, encephalopathy, disseminated intravascular coagulopathy, and renal failure.²⁰³

Diagnosis. Rickettsial organisms can be detected by immunofluorescence if biopsy is performed early in the course of disease or by restriction fragment length polymorphism analysis of a PCR product from the tache noire.^{116,196} *R. conorii* cannot be isolated from blood cultures by routine laboratory procedures. The clinical findings, geographic location, and epidemiologic considerations help establish the diagnosis.

The diagnosis can be established by one of multiple serologic tests that include complement fixation, latex agglutination, microagglutination, Western blot, and indirect IFA assays.^{57,79,173} An IFA assay for *R. conorii* is commercially available. Identification of specific immunoglobulin M (IgM) by immunofluorescence can identify acute infection, although some patients with proven MSF treated early with antibiotics have normal antirickettsial IgM levels.

Differential diagnosis. Before the rash appears, differentiation of MSF from other acute infections is difficult. Even after appearance of the rash, the disease can be confused with measles, meningococcemia, and secondary syphilis. Other rickettsial diseases should be considered, especially in the absence of a tache noire. Cross-reactions among rickettsiae occur with indirect immunofluorescence.

Treatment and prevention. MSF generally has a benign course, and fatalities rarely occur. Doxycycline is the drug of choice. Alternative regimens that have been effective in children include azithromycin 10 mg/kg daily for 3 days, clarithromycin 15 mg/kg twice daily for 7 days, and chloramphenicol 50 mg/kg 4 times daily for 7 days.^{26,31,207} The optimal duration of therapy has not been definitively established, however, and regimens ranging from single doses to treatment for up to 15 days have been reported.⁷⁰

The major effective methods of control involve avoidance of tick bites. Natural immunity occurs after infection, and antibodies persist for as long as 4 years after acute illness. Effective vaccines are not available.¹⁰⁹

Rickettsialpox

Historical aspects. First described in New York City in 1946 by Sussman as “Kew Gardens spotted fever,” rickettsialpox is a benign spotted fever group rickettsial disease caused by *R. akari*.^{82,84,167} Reporting of rickettsialpox declined in the latter decades of the 20th century; fewer than 50 cases were reported by the New York City Department of Health between 1980 and 1999. At least 34 cases were confirmed in 2001 and 2002, possibly as the result of increased awareness and detection of the disease after the bioterrorism anthrax attacks of 2001.¹²⁵

Organism. The etiologic agent, *R. akari*, is an obligate intracellular gram-negative coccobacillus that is morphologically identical to *R. rickettsii*. The principal vector is the house mouse mite, *Liponyssoides sanguineus*. Rodents, particularly the house mouse, *Mus musculus*, serve as a reservoir for *R. akari*.

Epidemiology and transmission. Most rickettsialpox in the United States has been reported from New York City, but cases also have occurred in many other cities in the United States and worldwide in Russia, Korea, and South Africa. Whereas house mice are the natural hosts of the mite transmitting rickettsialpox in the United States, rats have been shown to host the mite in Russia, and wild rodents are suspected of carrying the disease in South Africa. The reservoir for rickettsialpox may extend to additional, as yet unidentified, wild or domestic animals.

The disease has a natural cycle between the mite vector and the house mouse.⁸³ The mite passes the disease agent transovarially, and as such serves as both reservoir and vector. Depletion of rodent hosts from reduced food or pest control measures causes mites to feed on humans as an alternative host. The disease affects persons of all ages. Males and females are equally susceptible.^{20,69}

Pathology. Biopsy specimens from eschars are characterized by variable degrees of epidermal and dermal necrosis. Ulcerated lesions typically have neutrophils and thrombosed vessels in the ulcer base. The primary pattern of inflammation is a deep perivascular mononuclear cell infiltrate. Immunohistochemical staining reveals spotted fever group rickettsiae predominantly within the macrophages or mononuclear cells of the perivascular infiltrates associated with eschars or papules.⁹⁷

Clinical manifestations. The incubation period of rickettsialpox is 9 to 14 days after the usually painless mite bite occurs.^{20,90} The primary lesion is a papule that develops at the site of the mite bite. This lesion progresses through a papulonodular stage to a tense 0.5- to 2-cm vesicle that ruptures to form an eschar with surrounding induration, which is the hallmark of the disease.¹⁵⁵ Two eschars may be seen. Regional lymph nodes related to the primary eschar are almost invariably enlarged.

Constitutional symptoms develop approximately a week after the mite bite. Fever and malaise are commonly present. The fever is irregular, with temperature fluctuating between 37.8°C and 39.5°C (100°F and 103°F), and rarely lasts longer than 6 or 7 days. It usually is accompanied by the frontal headache characteristic of rickettsial diseases. Rhinorrhea, cough, sore throat, nausea, vomiting, and abdominal pain are occasional findings.⁶⁸

The rash is the most remarkable aspect of the disease. It usually develops within several days of the onset of fever as scattered nonpruritic macules, which rapidly become firm maculopapules. Within a day or two, vesicles develop on the summits of the papules. The lesions usually appear on the face, trunk, and extremities, with sparing of the palms and soles.¹⁹ The number of lesions ranges from 5 or 6 to more than 100.

Diagnosis. The diagnosis can be made by immunohistochemical staining of skin biopsy specimens, by PCR analysis of amplified gene products from eschars or culture of *R. akari* from eschars, and by serologic assays. These tests, used singly or in combination to establish the diagnosis, are available through the Centers for Disease Control and Prevention (CDC). A fourfold increase in serum antibodies to *R. akari* between acute and convalescent sera or a single titer of more than a 1:64 dilution is considered diagnostic. Cross-reaction is seen between antibodies to *R. akari* and *R. rickettsii*, but titers are greater with *R. akari* than with *R. rickettsii* antigen.¹²⁵

Differential diagnosis. Anthrax is a differential consideration. Rickettsialpox lacks the striking brawny, nonpitting edema surrounding the eschar that is characteristic of anthrax. Anthrax is not associated with the characteristic papulovesicular rash of rickettsialpox. The haphazard distribution of the characteristic papulovesicles is similar in appearance to chickenpox rash in an adult. Infectious mononucleosis, gonococcemia, and infection with echovirus or coxsackieviruses also should be considered.¹⁰⁴ Patients often give a history of having worked in basements, around incinerators, or in similar areas that might be infested by house mice and their mites.

Treatment. Rickettsialpox is a self-limited nonfatal disease that resolves within 7 to 10 days in untreated patients. Treatment shortens the duration of symptoms, usually to 24 to 48 hours.²⁰ Doxycycline is the drug of choice. A treatment course of 3 to 5 days is sufficient.

Other Spotted Fever Group Rickettsioses

A number of antigenically distinct *Rickettsia* spp. cause disease in humans. Among these, *R. parkeri* is perhaps the most important emerging rickettsial disease in the United States. This organism produces a mild spotted fever illness that may be difficult to clinically distinguish from mild RMSF.¹²⁴ In contrast with RMSF, an eschar is an important feature of *R. parkeri* infection. The vector for *R. parkeri* is the Gulf Coast tick, *Amblyomma maculatum*, which is most heavily concentrated in Gulf Coast and southeastern states. Whereas most cases occur in the Deep South, both infected *A. maculatum* ticks and at least one human case of *R. parkeri* infection have been reported from Virginia.^{58,193,202} Serologic assays in clinical use cannot distinguish *R. parkeri* from *R. rickettsii*. Whereas *R. parkeri* infection may be self-limited, it would be prudent to treat all suspected *R. parkeri* cases as if they are RMSF.

Another notable member of the spotted fever group is *Rickettsia africae*, the cause of African tick bite fever (ATBF). Evidence suggests that this is one of the most common acute febrile illnesses experienced

by travelers to Africa.⁸⁷ This disease has primarily been associated with travel to southern Africa and in particular travel in the game parks in this part of the continent.^{59,141} Its known range is broader, however, and includes much of sub-Saharan Africa. It is also endemic on some eastern Caribbean islands. Cattle ticks from the genus *Amblyomma* are responsible for transmission of the organism. The clinical hallmarks of ATBF are fever, headache, neck muscle myalgias, and an inoculation eschar with regional lymphadenopathy. Up to 50% of patients have multiple eschars that ascend along the lymphatic drainage.¹⁰³ Rash is unusual in ATBF. This is a benign infection and is probably self-limited in most cases. Doxycycline has been associated with rapid resolution.

Many other *Rickettsia* species are known to infect humans. *Rickettsia japonica* is the etiologic agent of Japanese spotted fever, *Rickettsia sibirica* of Siberian tick typhus, and *Rickettsia australis* of Queensland tick typhus. Dogs are the principal mammalian reservoir; ticks also act as reservoirs by virtue of transovarial transmission. Other newly recognized tick-borne diseases, such as *Rickettsia slovaca* infection, for which the wild boar is the main host, have been described in Europe.¹⁶ *Rickettsia felis* is transmitted by fleas, and its natural reservoirs are the opossum and the cat.¹⁸ The diseases caused by these and other rickettsial species have similar clinical, pathologic, and epidemiologic patterns. As with other rickettsioses, doxycycline is the preferred therapy.

TYPHUS

The rather imprecise term *typhus* is most commonly used to refer to three rickettsial diseases: epidemic typhus, murine or endemic typhus, and scrub typhus. Whereas the respective agents of epidemic and murine typhus, *Rickettsia prowazekii* and *Rickettsia typhi*, are phylogenetically related, scrub typhus is caused by *Orientia tsutsugamushi*, which is not even a member of the genus *Rickettsia*. To make matters more confusing, various spotted fevers are referred to as tick typhus (e.g., Queensland tick typhus, Siberian tick typhus).

Rickettsia prowazekii Infection (Epidemic Typhus)

Overview. Epidemic typhus is a louse-borne infection caused by *R. prowazekii*. Explosive epidemics of typhus are seen under conditions of overcrowding and extreme squalor. Typhus has been the suspected cause of some human epidemics dating back to the Dark Ages, but the first known epidemic occurred during the Spanish siege of Moorish Granada in 1489. Most sizeable typhus epidemics have struck during times of war. Outbreaks of typhus occurred throughout the world during the 19th century, famously ravaging Napoleon's army as it retreated from Moscow. Typhus afflicted thousands of soldiers during World War I, particularly on the eastern front. A devastating outbreak struck Russia during its civil war between 1917 and 1925, afflicting an estimated 25 million people and killing 3 million. During World War II, typhus killed tens of thousands as a result of the deplorable conditions in the Nazi ghettos, concentration camps, and prisoner-of-war camps. Typhus also struck combatants in the North African and Eastern European theaters.

The use of dichlorodiphenyltrichloroethane (DDT) in the 1950s resulted in a dramatic worldwide decline in typhus. Since then, it has reemerged predominantly in highland regions of sub-Saharan Africa and to a lesser extent Central and South America. Rwanda, Burundi, and Ethiopia have been particularly affected, certainly as a result of the coexistence of poverty and war.¹²⁸ In 1997 approximately 100,000 persons in Burundi were affected and as many as 15% died.^{14,144,146} A smaller outbreak occurred in Russia in 1997.¹⁷¹ Although autochthonous cases in the United States are rare, there have been at least 30 cases since 1976. These are most likely due to exposure to the flying squirrel (*Glaucomys volans*), which is a sylvatic reservoir for *R. prowazekii*.^{44,114,148}

Epidemiology and transmission. Humans are the primary reservoir for *R. prowazekii*. During interepidemic periods some people who previously survived typhus can be a reservoir of *R. prowazekii*. This is particularly true in persons with Brill-Zinsser disease, a form of relapsed typhus that can occur many years after the original infection.⁶⁴ The best established natural reservoir for *R. prowazekii* is the flying squirrel, *Glaucomys volans*, which is associated with sylvatic cases. These cases are recognized on rare occasion in the United States.¹³⁶ Lice that infest

flying squirrels will not bite humans, suggesting that human infection results from direct exposure to aerosolized louse feces.

The vector for epidemic typhus is the human body louse, *Pediculus humanus corporis*. The body louse inhabits clothing, from which it will take blood meals from its host. Frequent blood meals are required because the louse is sensitive to dehydration. It is also sensitive to deviations from normal human body temperature, such as fever. Cold conditions, in which humans have more clothing and blankets, will increase louse habitat. Lice will not survive for long away from a suitable host, so impoverished persons who do not have changes of clothing will be most heavily parasitized. Lice will proliferate under these conditions, and a single person may be infested by thousands of lice. Lice will readily pass between people under crowded and unhygienic conditions. A heavily infested person who develops typhus can infect thousands of lice, which will promptly seek a new host once fever develops. Because each infected person can secondarily infect many others, there can be explosive epidemic potential under conditions of both high human density and heavy louse infestation.

R. prowazekii incubates in the louse for 5 to 10 days after it bites an infected person. Great numbers of rickettsiae are then shed in louse feces.¹⁴⁵ Because the louse defecates as it feeds, infectious feces can be rubbed into a louse bite wound. The bodies of crushed lice are also infectious. Dried louse feces can be aerosolized and cause infection through the eye or the respiratory tract.

Pathogenesis. The organism initially spreads through lymphatics and the blood to infect small vessel endothelial cells in a wide variety of target organs.⁹ Intracellular proliferation of the organism results in mechanical cell lysis, producing widespread vasculitis and capillary leak.

Clinical manifestations. Illness begins after a 10- to 14-day incubation period. An initial period of malaise is followed by high fever, headache, and rash.⁴ Body temperature generally rises rapidly to 40°C (104°F) or higher. In untreated patients, it remains at this level with minor fluctuations until death or recovery occurs. Headache is common and may be severe or intractable. Cough is also a frequent complaint. The rash usually appears on the trunk by the fourth to seventh day; it spreads peripherally to the extremities and typically spares the face, palms, and soles. Initially, the rash consists of macules that fade on pressure; they soon become fixed as maculopapules and later become petechial or hemorrhagic. Rash is less frequently recognized in individuals with dark skin. Central nervous system manifestations are described in up to 80% of patients, including delirium, coma, seizures, and hearing loss.⁶¹ Other complications include parotitis, otitis media, pericarditis, myocarditis, pericardial effusion, pleural effusion, and pneumonia.^{40,199,200} Severe cases of typhus can be manifested with shock or with tissue ischemia, including gangrene. Mortality was as high as 60% in the preantibiotic era and is higher in malnourished populations and elderly people. With appropriate antibiotics, the mortality is approximately 4%. Recrudescence infection (Brill-Zinsser disease) can occur years after the primary infection if it is not eradicated. Because of partial immunity, Brill-Zinsser disease is milder than primary typhus.

Diagnosis. Typhus is diagnosed with evidence of seroconversion. A fourfold rise in IgG antibody titer is considered diagnostic. This requires paired acute and convalescent sera. Several testing methods are available, but the preferred method is indirect IFA assay.^{99,122} IFA assay will not discriminate epidemic from murine typhus (*R. typhi* infection); discrimination between the two infections requires Western blotting with cross-adsorption.¹⁰⁰ Shell vial culture can detect *R. prowazekii* from blood specimens.¹³ The Weil-Felix agglutination test is no longer recommended because of lack of specificity (due to cross-reactivity) and poor sensitivity in Brill-Zinsser disease.

Differential diagnosis. Typhus may be difficult to distinguish from other acute febrile illnesses, especially early in the course of disease. Depending on the local epidemiology, these can include typhoid fever, dengue, malaria, influenza, leptospirosis, and other rickettsial illnesses. The rash of louse-borne typhus begins centrally on the trunk and spreads peripherally to the extremities, whereas the reverse is true for RMSF. Moreover, a rash on the palms and soles, a common event in RMSF, rarely is observed in typhus.

Treatment. Doxycycline is the treatment of choice for epidemic typhus.⁹⁸ Therapy is given until the patient is afebrile for at least 3 days

and clinical improvement is evident; the usual duration is 7 to 10 days. Lack of defervescence after 3 days suggests an alternative diagnosis. Single-dose therapy with doxycycline 200 mg has been effective in epidemic settings.¹²⁹ Chloramphenicol is an alternative agent for those with a serious contraindication to doxycycline. As with other rickettsial infections, the risk for tooth staining is negligible for young children receiving this degree of doxycycline exposure; moreover, the potential lethality of typhus justifies the use of doxycycline in children in whom the diagnosis is plausible. Whereas fluoroquinolones have in vitro activity, there has been a treatment failure with ciprofloxacin resulting in death.²⁰⁴

Prevention. DDT was effective at limiting the burden of typhus in the 1950s. Its use has been long banned by many countries. Along with DDT, malathion and permethrin are also effective at eradicating lice from infested clothing and bedding. Lice will die within days if they do not have access to a host, so removal of infested clothing for 1 week may suffice.¹⁴⁵ Relief workers assisting persons at risk for typhus can pretreat their clothing with permethrin. Doxycycline prophylaxis appears to be effective in select populations at risk for scrub typhus; whether this is true for epidemic typhus remains unknown.

Rickettsia typhi Infection (Murine Typhus)

Overview. Murine typhus, also known as flea-borne or endemic typhus, is a flea-borne zoonosis primarily of rats, opossums, and cats. The disease occurs worldwide, especially in warm climates where rats or opossums are abundant. During the early 20th century, there were thousands of annual cases of murine typhus in the United States, particularly along the Gulf Coast and the southern Atlantic seaboard. In recent years, 60 to 80 cases have been reported annually, most of which are from southern California, the southeastern Gulf Coast including Texas, and Hawaii.^{1,54} The actual incidence in the United States is unknown. Approximately 0.6% of children in south-central states have an *R. typhi* titer of greater than 1:64.¹¹⁰ The seroprevalence in southeastern Texas may be as high as 15%. These figures suggest that murine typhus is considerably underrecognized in certain regions.^{54,137,194}

Epidemiology and transmission. *R. typhi* infection is a vector-borne zoonosis that persists in a flea-mammal cycle in nature. The classically described cycle involves the Oriental rat flea, *Xenopsylla cheopis*, and peridomestic rats. Rat infestations, especially near granaries and ports, pose a risk for human contact. A more recently described transmission cycle involves the cat flea, *Ctenocephalides felis*, and opossums or domesticated cats as their primary mammalian host. This cycle seems primarily responsible for ongoing transmission of both *R. typhi* and *R. felis* in suburban regions of southern California and south Texas.^{1,11,160} Uninfected fleas acquire the organism from infected mammals and can transmit it to new hosts, including humans; in turn, an infected mammal can serve as a reservoir for many fleas. Rickettsiae multiply and reside in both the digestive and reproductive tracts of the flea, which is unaffected by the organism. The flea goes on to produce highly infectious feces for the rest of its life. It can also pass the organism transovarially to its offspring. Humans are not the preferred hosts for fleas, but the cat flea in particular will readily bite humans. If the flea bites a person, infection typically occurs when flea feces are rubbed into the bite wound; it can also be inoculated by direct contact or by aerosol to mucous membranes.

Clinical manifestations. Murine typhus is clinically similar to epidemic typhus (*R. prowazekii* infection), but it is milder, of shorter duration, and less likely to be severe or fatal. Symptoms develop after a 5- to 10-day incubation period, although an antecedent flea bite is not always reported. All affected patients develop fever, and most have headache or rash.¹⁹² The classic triad of fever, headache, and rash occurs in half of patients. This may be because rash typically appears between days 3 and 10 of illness and may not be present when patients first seek medical attention. Other common symptoms include malaise, myalgias, and vomiting. Rashes are typically macular or maculopapular; only in rare cases have they been described as petechial. Laboratory abnormalities are inconsistently reported, but the most common include elevated hepatic transaminases and mild hyponatremia.^{54,160} Children who receive appropriate antibiotics undergo defervescence in 1 to 3 days. Even without appropriate treatment, murine typhus is generally self-limited, with recovery in 1 to 2 weeks and a very low rate of complications.^{54,160}

Diagnosis. A fourfold change in titer between acute and convalescent sera by indirect IFA assay, latex agglutination, complement fixation, or enzyme immunoassay is diagnostic. Differentiation among antibodies produced in response to epidemic typhus is difficult but may be accomplished by use of an IgM-specific enzyme immunoassay, if needed. Immunohistochemical staining or PCR analysis of amplified gene product of tissues and culture, available through the CDC, also can be used for confirmation.

Differential diagnosis. Murine typhus is an undifferentiated acute febrile illness and resembles numerous other infections. In the United States, these include but are not limited to enteroviral disease, other viral exanthems, other rickettsial diseases, and group A streptococcal infection. A history of recent travel to tropical or developing countries could expand the differential diagnosis to include other febrile illnesses, such as malaria, dengue, typhoid fever, and leptospirosis.

Treatment. Doxycycline is the treatment of choice for murine typhus. Chloramphenicol is an alternative in patients with an important contraindication to tetracyclines. Whereas fluoroquinolones have been used successfully to treat *R. typhi* infection, at least one treatment failure has been documented.^{101,165} Treatment should be continued for at least 3 days after defervescence and evidence of clinical improvement; this is typically 3 to 7 days.

Prevention. Rat control measures can lower the likelihood of human disease in areas where *R. typhi* is transmitted.

Scrub Typhus

Overview. Scrub typhus is a mite-borne rickettsial disease that exclusively occurs in the Asia-Pacific region. This infection may have been recognized as early as the 3rd century AD and was the subject of non-Western medical writing in Japan during the 19th century.¹¹⁸ In the South Pacific theater of World War II, scrub typhus was second only to malaria as a cause of fever, affecting more than 16,000 Allied soldiers.^{118,131} It remained an important pathogen among febrile American soldiers in the Vietnam conflict.^{10,77}

Organism. The causative organism, *Orientia tsutsugamushi*, was formerly a member of the genus *Rickettsia*. In 1995 it was reclassified to the novel genus *Orientia* on the basis of distinctive phenotypic and genetic features.¹⁶⁵ *O. tsutsugamushi* is distinguished by remarkable antigenic heterogeneity. Strain differences also appear to contribute to striking differences in its severity.

Epidemiology and transmission. Scrub typhus is widely distributed throughout central, eastern, and southern Asia. It is transmitted as far north as Kamchatka in eastern Russia and as far west as Pakistan and Afghanistan. Its southern range includes the islands of Indonesia and Oceania as well as northern Australia.⁹¹ The disease is distributed according to the habitat of its vectors, which in turn are distributed in widely diverse habitats. Scrub typhus has been described from sea level to alpine meadows above 3000 meters in elevation, in both arid and humid environments, in a variety of agricultural regions, and more recently in cities.^{157,166,177,178} Humans are most likely to encounter chiggers in undergrowth in rural areas. Travelers engaged in outdoor activities, such as camping and trekking, are at risk for acquiring scrub typhus; some of these individuals do not become clinically ill until after return to their home country.^{80,157}

Trombiculid mites from the genus *Leptotrombidium* are the vectors for scrub typhus. Only the six-legged larvae, known colloquially as chiggers, will feed on humans. The eight-legged nymphs and adults feed on plant matter and do not parasitize mammals. Wild rodents, particularly rats, are the preferred host for chiggers and are important in the ecology of scrub typhus. The rodents, however, are not thought to be a natural reservoir for *O. tsutsugamushi*, and in fact each mite feeds on a mammalian host only once in its life. Rather, the microorganism persists transstadially (across life cycle stages) within the mite and is passed transovarially to subsequent generations.^{60,168,182} Thus the mite itself is the natural reservoir for this pathogen.

Pathogenesis. *O. tsutsugamushi* primarily infects endothelial cells and mononuclear leukocytes. Human autopsy specimens have shown endothelial cells infected with microorganisms in numerous organs, including brain, heart, kidney, and lung.¹¹⁷ They have also been found in macrophages and in cardiac muscle cells. Dissemination from the

inoculation site to target organs may occur through infected peripheral blood mononuclear cells.¹⁸⁶ Infection of monocytes induces a robust inflammatory cascade that may be responsible for tissue injury and both systemic and organ-specific disease manifestations.^{96,170} There are marked differences in disease severity and mortality, and these are likely due to strain variations. The phenotypic factors responsible for this variability are poorly understood.

Clinical manifestations. In one-half to two-thirds of cases, the initial mite bite lesion develops into a necrotic eschar. In adults eschars are most commonly found on the trunk⁹⁴; in children they are seen commonly in moist intertriginous areas such as the genitalia and perineum.¹⁵⁹ The incubation period is approximately 1 to 2 weeks, and characteristic features of the disease develop at approximately the same time that the eschar is noted. A scar often persists at the site of the eschar.¹⁹⁰

Fever is nearly universal. Common clinical findings include hepatomegaly, respiratory distress, and lymphadenopathy. Among 30 children presenting with febrile illness of at least 5 days' duration in Thailand, common physical signs included lymphadenopathy (93%), hepatomegaly (73%), eschar (68%), conjunctival hyperemia (33%), maculopapular rash (30%), interstitial pneumonia (30%), and splenomegaly (23%).¹⁵⁹ In a separate series of 60 Sri Lankan children, the most common findings in patients with confirmed scrub typhus were hepatomegaly (95%), generalized lymphadenopathy (60%), respiratory distress (45%), and splenomegaly (35%).³⁷ Hepatomegaly was observed in 80% and cough in 73% of Indian children with scrub typhus.¹²⁶ Patients can present with either transudative or exudative pleural effusions.⁹² Nervous system disease can manifest as aseptic meningitis, meningoencephalitis, or cranial or peripheral neuropathies. Severe complications include myocarditis, disseminated intravascular coagulation, and the acute respiratory distress syndrome.^{119,126} The severity and lethality of scrub typhus can vary widely.

Diagnosis. The mainstay of scrub typhus diagnosis is serologic testing. The gold standard is the indirect IFA assay; however, there is little consensus in IFA methodology and positivity cutoff limits. Blacksell and colleagues reviewed the evidence base for various methodologies and the criteria for positive IFA assay results and concluded that the diagnosis should be based on a fourfold or greater increase in the IFA titer in paired serum specimens and on a single sample only when there is an adequate local evidence base.¹⁵ The limited number of source strains used for IFA assay antigen may be inadequate given the enormous antigenic diversity and geographic heterogeneity of *O. tsutsugamushi*.⁹¹

Other tests, such as enzyme-linked immunosorbent assay, dot immunoassay, indirect immunoperoxidase, and Weil-Felix OX-K assay, are also used.^{86,120} The last is the most commonly used diagnostic modality in developing countries; however, this assay lacks both sensitivity and specificity. OX-K agglutinins develop in only a little more than 50% of scrub typhus patients. Moreover, OX-K agglutinins also are produced in relapsing fever.

Identification of the rickettsial strain in infected patients by use of strain-specific monoclonal antibodies in an inhibition enzyme-linked immunosorbent assay or PCR with strain-specific primers offers potential to establish the diagnosis in the acute stage of the illness.^{62,63} An eschar PCR assay, evaluated prospectively, demonstrated high sensitivity and specificity compared with IFA assay.⁹³ Cell culture and xenodiagnosis-based assays are expensive and laborious and are not available clinically.

Differential diagnosis. Scrub typhus can be suspected when a patient gives a history of recent exposure in a geographic area where scrub typhus occurs. If, in addition, a local eschar, evanescent rash, and general and regional lymphadenopathy along with fever, headache, and conjunctival suffusion are present, the physician should be alerted to suspect scrub typhus; however, it cannot be differentiated with certainty from other febrile illnesses that occur in the region. These include but are not limited to dengue, chikungunya, leptospirosis, malaria, typhoid fever, and other rickettsioses such as murine typhus.

Treatment. Doxycycline is the treatment of choice. Children have responded well to treatment for 4 to 7 days.¹⁵⁹ Doxycycline is rickettsiostatic, and patients with scrub typhus who are treated in the first week of illness can require sporadic short courses of antibiotic therapy for prevention of relapse.¹⁷⁹ Chloramphenicol, azithromycin, and rifampin are alternatives.^{95,127,133} Strains with reduced susceptibility to antibiotics

have been observed in northern Thailand.¹⁸⁷ In one study from this region, rifampin was found to produce a significantly faster clinical response than did doxycycline.¹⁸⁸

Prognosis. The prognosis varies widely because of significant differences in the severity of disease caused by different strains in different populations and in various geographic areas. Mortality rates in the preantibiotic era ranged from 1% to 60%. With the use of antimicrobials, fatalities rarely occur. When treatment is begun early in the course of scrub typhus, relapses as well as definite second attacks of the disease can occur. The heterogeneity of scrub typhus strains probably accounts for reinfections.

Prevention. Vector control involves impregnating clothing and smearing exposed skin surfaces with dimethyl or dibutyl phthalate. Short-term vector control of camping grounds can be accomplished by cutting, burning, or bulldozing vegetation, along with heavy spraying with insecticides such as lindane. Chemoprophylaxis is feasible for persons with high-risk exposure for short periods. Doxycycline given once a week may provide effective chemoprophylaxis against naturally transmitted scrub typhus if the prophylaxis is started before exposure to infection and continued for 6 weeks after exposure.¹⁷⁹ A recent report, however, showed that prophylactic failures can occur and are not associated with antimicrobial resistance.⁷⁴ No satisfactory vaccine has been produced.

EHRlichiosis and ANAPLASMOSIS

Overview. Ehrlichiosis and anaplasmosis are tick-borne infections caused by rickettsial organisms from the genera *Ehrlichia* and *Anaplasma*. Strictly speaking, they are best thought of as anaplasmoses because both genera are members of the family Anaplasmataceae of the order Rickettsiales. Six members of this family are known to infect humans: *Ehrlichia chaffeensis*, *Ehrlichia ewingii*, *Ehrlichia canis*, *Ehrlichia muris*-like, *Anaplasma phagocytophilum*, and *Neorickettsia sennetsu*. The last two were formerly members of the genus *Ehrlichia*; *A. phagocytophilum* was reclassified to its own genus in 2001.⁴⁶

Unlike many rickettsial infections, which have been recognized for decades if not centuries, ehrlichiosis and anaplasmosis are emerging diseases that have been only recently identified. From 1953 until the late 1980s, the only known human infection from this group was Sennetsu fever, a mild febrile illness in East Asia caused by *Neorickettsia* (formerly *Ehrlichia*) *sennetsu*. The disease that ultimately became known as human monocytic ehrlichiosis (HME) was first described in humans in 1986, and it was suspected that this was due to *E. canis*, a known veterinary pathogen.^{50,107} It was not until 1991 that its primary cause, *E. chaffeensis*, was identified.⁴ Human ehrlichiosis can also be caused by *E. ewingii*, *E. canis*, and an *E. muris*-like organism.^{22,135} In the early 1990s, the syndrome now known as human granulocytic anaplasmosis (HGA) was identified in the upper Midwest; its cause, *A. phagocytophilum*, was recognized in 1994.³⁰

Organisms. *Ehrlichia* and *Anaplasma* are small gram-negative obligately intracellular bacteria. *E. chaffeensis* propagates in macrophages; *A. phagocytophilum* and *E. ewingii* multiply in neutrophils.

Epidemiology and transmission. The incidence for both HME and HGA has increased substantially during the last decade, although this may be partly a function of increased recognition. These infections have also been reportable only since the late 1990s, which suggests that some of the increased incidence is a function of more complete reporting and case ascertainment practices. There is also annual variation in the incidence of both diseases, which lacks a satisfactory explanation. Nonetheless, hundreds of persons are affected annually. In 2009 there were 944 cases of HME and 1161 cases of HGA.²⁸ In 2010 there were 740 cases of HME and 1761 cases of HGA. The prevalence of *E. chaffeensis* titers of 1:160 or higher was 3% among children residing in the southeast and south-central regions of the United States, suggesting that exposure is far more common than is the incidence of recognized disease.¹¹¹

The geographic distributions of both HME and HGA are tied to the distribution of their respective tick vectors. The lone star tick, *Amblyomma americanum*, is the principal vector of HME and *E. ewingii* ehrlichiosis. This aggressive tick is by far the most common “pest” tick in the southern and southeastern United States.^{24,32,66,115} In low numbers,

its range extends as far north as New England, but it is particularly abundant in Missouri, North Carolina, and states farther south. All active stages of the tick will readily bite humans. Individuals can become multiply parasitized by larval ticks (known colloquially as seed ticks). The adult female tick is easily recognized by a conspicuous light-colored spot, but this marking is not present on males or on immature ticks. HME is transmitted in the eastern half of the United States, from the Great Plains to the Atlantic Coast. Oklahoma, Arkansas, and Missouri together account for 35% of all cases.¹⁰⁵ Southeastern and mid-Atlantic states account for most of the remainder, but HME acquisition is well documented in Delaware and New Jersey and occasionally occurs even in coastal New England. There is also serologic evidence of HME transmission in Central and South America. The white-tailed deer is the most likely natural reservoir for *E. chaffeensis*.¹⁰⁵

HGA, by contrast, is transmitted in North America, Europe, and Asia. In the United States, it primarily occurs in northeastern states, from New Jersey through northern New England, as well as in Minnesota and Wisconsin in the upper Midwest.¹⁰⁵ The black-legged or deer tick, *Ixodes scapularis*, is the vector for HGA. *A. phagocytophilum* is maintained in nature in a tick-mammal cycle that primarily involves small rodents.^{27,172} Whereas adult *I. scapularis* ticks will occasionally feed on humans, it is primarily the nymph whose feeding habits make it a vector for human infections. The nymph is most active in late spring and early summer. Because this immature stage of the tick is quite small, a tick bite often will go unrecognized. HGA shares a vector with Lyme disease, and there is evidence that the endemic range for Lyme disease is expanding; this may portend further expansion of the anaplasmosis-endemic zone as well. HGA is rarely acquired in California, where the Western black-legged tick (*Ixodes pacificus*) is the responsible vector. In Europe, it is transmitted by *Ixodes ricinus*; in Asia, its vector is *Ixodes persulcatus*.

Both anaplasmosis and ehrlichiosis are predominantly transmitted from May through October, in conjunction with the peak activity of their tick vectors. In contrast to other tick-borne diseases such as Lyme disease and RMSF, in which children have among the highest incidence rates, it is older adults who suffer the highest incidence of HGA and HME.

Pathogenesis and pathology. The pathogenesis of ehrlichiosis is incompletely elucidated. Although it is capable of establishing infection in numerous organs and tissues, the primary target cell for HGA is the granulocyte; for HME, it is the macrophage. Granulomas of the bone marrow occur frequently in HME, suggesting that involvement of the reticuloendothelial system may be important in pathogenesis.⁴⁷

Organisms enter the cytoplasm of host cells and proliferate in phagosomes into elementary bodies. These individual organisms multiply by binary fission into immature inclusions called initial bodies. Mature groups of elementary bodies form morulae, which are released by rupture of the cell to reinstate the infecting process.¹⁰⁷

Clinical manifestations. Most patients become clinically ill within 2 weeks of exposure. HME and HGA are acute febrile illnesses in which fever and malaise are universal symptoms.^{45,48,56,130} Headache, myalgia, arthralgias, and nausea are also common. Confusion occurs in about 20% of patients with HME, primarily among older adults; this symptom is less common in HGA. Rash is more common in ehrlichiosis than in anaplasmosis and primarily occurs in children. Rashes can be macular, maculopapular, or petechial and seldom develop in adult infections. Rashes are reported in about 30% of cases of HME, compared with 10% or less in HGA.

Meningitis as a manifestation of HME has been reported in children. Symptoms can range from irritability and meningismus to obtundation with response only to painful stimuli.^{11,42,67} Initial examination of cerebrospinal fluid reveals pleocytosis ranging from approximately 50 to 1400 white blood cells, usually with a predominance of mononuclear cells; a range of 5 to 40 red blood cells; mildly elevated protein concentration; and a normal to slightly low glucose value. Complete recovery is the rule. Central nervous system involvement is much less common in HGA.

The most common laboratory findings in both infections are hematologic abnormalities and elevated hepatic transaminases.⁴⁵ Thrombocytopenia is seen in three-fourths of patients, leukopenia in two-thirds, and anemia in one-half. In HME, the leukocyte abnormalities

are primarily lymphopenia and monocytopenia. In HGA, neutropenia is more common, especially with illness of longer duration. Elevations of hepatic transaminases are seen up to 80% of the time in both HGA and HME.

A variety of complications may be seen in both infections. These include protracted fever, renal dysfunction occasionally of sufficient severity to require dialysis, acute respiratory distress syndrome, myocarditis, neuropathies and plexopathies, opportunistic infections, and a toxic shock–like syndrome.^{45,55,153} Whereas persistent infection is much better documented in reservoir hosts, there has been a case report of fatal, treatment-refractory persistent infection in an older adult, although relapse after doxycycline therapy is thought to be otherwise unheard of.¹²³ There is one case report of fatal seronegative HME in a patient with advanced HIV infection.¹²³ Up to one-half of patients with HME or HGA require hospitalization. The mortality rate is 3% for ehrlichiosis and 0.5% for anaplasmosis.

Diagnosis. In contrast to RMSF and other infections with agents in the genus *Rickettsia*, anaplasmosis and ehrlichiosis are primarily infections of circulating leukocytes. This potentially allows the diagnosis to be made at the point of care or during the patient's clinical illness. Peripheral blood smear examination will reveal morulae in neutrophils in 25% to 75% of patients with HGA; intramonocytic morulae are seen in 10% or less of patients with HME.^{6,7,162} Whereas the sensitivity of this examination is low, a positive blood smear is pathognomonic and will allow a real-time diagnosis. PCR amplification of a peripheral blood specimen is a more sensitive alternative for both anaplasmosis and ehrlichiosis; it is also the only modality available for the specific diagnosis of *E. ewingii* infection. Reported sensitivities range from 60% to 85% for HME and 67% to 90% for HGA.^{5,7,81,121} These assays are available from some clinical laboratories. The sensitivity of both blood smear examination and PCR is abrogated by antecedent doxycycline treatment.

Serology by indirect IFA assay remains the most sensitive and widely used means to diagnose ehrlichiosis and anaplasmosis. Paired acute and convalescent sera must be obtained, and a fourfold rise in antibody titer is considered diagnostic. The reported sensitivity is 88% to 90% for HME and 82% to 100% for HGA.^{35,121,185} Antibodies to *Ehrlichia* and *Anaplasma* may be cross-reactive, so simultaneous serologic testing for both infections is preferred. The use of paired acute and convalescent sera must be emphasized for two reasons: (1) a single acute serum specimen will yield a positive result in only 3% of cases; and (2) a positive titer at a single time point may be due to prior infection, asymptomatic seropositivity, or cross-reactivity to other infectious agents.^{8,121,185}

Differential diagnosis. A variety of febrile illnesses can be indistinguishable from ehrlichiosis and anaplasmosis, especially early in infection. The most common symptoms of fever, headache, and malaise are generic. A careful history, exposure assessment, and physical examination can help limit the differential diagnosis. Differential considerations include but are not limited to viral infections (e.g., enteroviruses, adenoviruses) and bacterial infections (including septic and toxic shock syndromes and focal bacterial infections such as pneumonia that have not yet manifested focally). A number of tropical infectious diseases can have similar clinical presentations and laboratory findings; these include dengue virus infection, typhoid fever, malaria, and leptospirosis.

HME and HGA must be distinguished from other tick-borne diseases, in particular RMSF. Compared with RMSF, these infections are less likely to be accompanied by rash and more often are associated with leukopenia or pancytopenia. The similarity of ehrlichiosis and RMSF is emphasized by two retrospective serosurveys in which approximately 10% of specimens from patients lacking the serologic criteria for a diagnosis of RMSF fulfilled diagnostic criteria for ehrlichiosis.^{73,152} Other tick-borne illnesses, such as babesiosis, Colorado tick fever, relapsing fever, and tularemia, should be included in the differential diagnosis. In fact, the only major tick-borne infection in North America that is unlikely to be confused for HGA or HME is Lyme disease because high fever and systemic toxicity would be unusual for this infection.

Treatment. The drug of choice for treatment of human ehrlichiosis and anaplasmosis is doxycycline. The recommended dosage is 2.2 mg/kg twice daily (maximum adult dose, 100 mg twice daily). Treatment should

continue for at least 3 days after defervescence for a total course of 5 to 14 days.^{174,201} Because both infections may be severe or fatal, doxycycline treatment should be initiated when the diagnosis is suspected, without regard for the age of the child. Severe cases can require a longer course of treatment. Rifampin is an alternative that can be used in pregnancy and in early childhood, particularly when the index of suspicion for anaplasmosis or ehrlichiosis is low. There is contradictory in vitro evidence about fluoroquinolones, and these are not recommended for the treatment of either infection. Prophylactic treatment after tick bites is discouraged for the prevention of HGA, HME, or other tick-borne rickettsial illnesses.

Coinfection. HGA shares the same tick vector and geographic distribution as *Borrelia burgdorferi* and *Babesia microti*, the agents of Lyme disease and human babesiosis. Simultaneous coinfection with two or even three of these pathogens occasionally occurs and is well described. Because Lyme disease is by far the most common of these three, one should consider coinfection in patients who have Lyme disease that is accompanied by atypically high fever, systemic toxicity, uncharacteristic laboratory abnormalities, or poor response to therapy. Doxycycline therapy for anaplasmosis will be active against *B. burgdorferi*, but the duration of therapy may be shorter than that recommended for early Lyme disease (typically 10–14 days). Treatment of babesiosis requires either clindamycin with quinine or atovaquone plus azithromycin.

Q FEVER

Historical aspects. Q fever (the “Q” is for “query”) was first described by Edward Derrick as part of an investigation of an apparently infectious febrile illness in 1937.³⁹ The cause of Q fever was discovered in the late 1930s independently by Burnet and Freeman in Australia and by Cox in the United States. The organism was named *Coxiella burnetii* in honor of two of the discoverers. Infection with *C. burnetii* is worldwide in distribution and is often asymptomatic. When it causes symptoms, the disease is Q fever; it is typically an influenza-like acute illness characterized by fever, headache, fatigue, and myalgias.¹⁷⁶ It can also cause a difficult to diagnose chronic infection, particularly in patients with preexisting valvular heart disease.

Organism. *C. burnetii* is a small gram-negative coccobacillus that looks like most rickettsiae. However, it has recently been reclassified in the Gammaproteobacteria on the basis of 16S rDNA studies (order: Legionellales) and is now understood to be relatively closely related to *Legionella pneumophila*.^{102,164} *C. burnetii* is an intracellular pathogen that multiplies within phagosomes in the cells it infects, in contrast to the rickettsiae, which can live independently in the cytoplasm or nucleus of infected cells. It is believed that *C. burnetii* is the only intracellular pathogen that is able to neutralize the acidic, degradative environment of eukaryotic polyphagolysosomes.⁷⁸ Its life cycle is distinctive in that it produces endospores that are similar to those seen in some gram-positive organisms.¹⁵⁸ These small cell variants protect the organism in the external environment, where it can survive for long periods.¹⁷⁶

C. burnetii is also distinctive because it exhibits antigenic phase variation. Phase I variants are associated with mammalian infection and are highly contagious; phase II variants, of reduced virulence, follow propagation and are associated with a chromosomal deletion that results in a partial loss of lipopolysaccharide that makes the organism noninfectious.¹⁴³

Epidemiology and transmission. Q fever is distinct from human rickettsial infections in that it is primarily a disease of animals that is transmitted to humans by contact with infected animals rather than by an arthropod bite. It infects a broad range of animals including mammals, birds, and arthropods (mostly ticks). The most common sources of human infection are cattle, goats, and sheep, but pets (including dogs, cats, rabbits, and pigeons) can be vectors.¹⁷⁶ *C. burnetii* organisms are found in very high concentration in the placentas of infected parturient animals and are shed into the environment after labor or abortion.¹⁰² Transmission of infection to humans is through aerosols. Unfortunately, the organisms can be wafted by the wind and infect people with no known exposure.¹⁷⁵ Epidemics have occurred in a variety of situations like abattoirs, tanneries, and shearing camps in rural areas. Cases have been reported of

schoolchildren who went to farms on field trips.¹⁰⁸ Laboratory outbreaks are also a concern,⁷¹ and the organism should be cultivated only in a biosafety level 3 laboratory.¹⁰²

Outbreaks of Q fever can occur and cause massive public health ramifications. There was, for example, an epidemic of more than 2200 cases in the Netherlands in 2009 that resulted in the prophylactic slaughter of 50,000 dairy goats in an attempt to end the outbreak.¹⁰⁶

Pregnant women can transmit the infection to their infants, although the risk for abortion with Q fever is considerable. Those infants not aborted are likely to be delivered prematurely or to have low birth weight.¹⁴⁰

The prevalence of human Q fever is unknown. The diagnosis is difficult to make, and systematic epidemiologic evaluations are few and overreliant on antibody testing in subjects with variable suspicion of disease. The number of reported cases (an average of 50 to 60 cases per year to the CDC) almost certainly substantially underestimates the actual incidence.¹³⁹ The disease has been diagnosed in children younger than 3 years and should be considered during an evaluation for fever of unknown origin.¹⁴⁹ However, Q fever is quite uncommon in the United States, with an average of 40 cases per year reported in the United States, and very few cases in children younger than 15 years.³⁴ In that 2015 survey, an exposure to raw milk was noted as a risk factor for Q fever disease.

Pathology. Mortality from Q fever is rare, so autopsy specimens are relatively uncommon. Pathologic series obtained during outbreaks described liver and bone marrow disease, in which distinctive fibrin-ring and lipid granulomas were seen. Granulomas have also been seen in the lungs at autopsy. The cellular response was thought to be primarily histiocytic.¹⁶¹ Biologic control of *C. burnetii* requires a T-cell response, and patients with impaired cellular immunity (cancer patients, HIV-infected people) are at high risk for chronic infection.¹⁰²

Clinical manifestations. Q fever is manifested in both acute and chronic forms. The most common outcome of *C. burnetii* infection is an asymptomatic seroconversion. Symptomatic Q fever is particularly uncommon in children; infected adults are more likely to be symptomatic than children.¹⁷⁶ Using standard diagnostic criteria, in 2002, Maltezos and Raoult could identify 46 published pediatric cases (many patients previously described did not meet current standards for diagnosis). The most common manifestations in children were fever and pneumonia. Other common manifestations were febrile seizures, meningeal irritation, malaise, lymphadenitis, and anorexia. The fever was typically sustained for 5 to 10 days.¹⁰⁸ Q fever myocarditis has been diagnosed in three pediatric patients.

In adults, acute Q fever is manifested as an influenza-like syndrome with the abrupt onset of high fever, fatigue, headaches, and myalgias. Atypical pneumonias can occur, but the chest radiograph is usually normal and the primary manifestation is a nonproductive cough. Hepatitis is common, although it appears to be regionally distributed (some areas have more pneumonia, some more hepatitis). Maculopapular and purpuric rashes are seen in 10%, and myocarditis (although rare) can be potentially fatal.¹⁷⁶

Chronic Q fever most often occurs in patients with some form of immune compromise. In particular, patients with T-cell defects, pregnant women, and patients with abnormal heart valves are at risk for chronic Q fever. It occurs in 1% to 5% of *C. burnetii*-infected patients, symptomatic and not, and may develop months or years after the primary infection.¹⁷⁶ Q fever endocarditis is manifested with low-grade fever, nonspecific cardiac findings, and a positive antibody test response for *C. burnetii*. It occurs primarily in patients with preexisting valvular disease. A 2002 review article found five cases of pediatric Q fever endocarditis, all of which had vegetations on the child's heart valves. The diagnosis is made serologically. *C. burnetii* was demonstrated on the valves from two of the cases. Q fever osteomyelitis has also been rarely seen in normal children.

Q fever can be severe during pregnancy; 33 confirmed cases were investigated, and in only 5 cases was there a normal pregnancy and healthy term delivery.¹⁰⁸ A subsequent study identified 53 pregnant women with Q fever. Eighty-one percent of patients who were not treated with long-term trimethoprim-sulfamethoxazole therapy had complications: 5 had spontaneous abortions, 10 experienced intrauterine

fetal deaths, 10 had fetal intrauterine growth restriction, and 10 were delivered prematurely. Patients treated with long-term trimethoprim-sulfamethoxazole therapy were protected from chronic maternal Q fever, placental infections, and obstetric complications.²⁵

Diagnosis. *C. burnetii* can be diagnosed by several techniques, but for practical reasons the primary diagnostic modality is serology. The most commonly used test is an IFA assay. The test is actually directed at detection of antibodies against phase II antigens, the nonpathogenic form of the organism. Antibodies peak 4 to 8 weeks after the onset of disease. Detection of anti-phase I antigens is used in the diagnosis of chronic Q fever (e.g., endocarditis, osteomyelitis) because in chronic Q fever, the level of anti-phase I antibodies will exceed anti-phase II antibodies.¹⁰² Culture of *Coxiella* is possible, but because of the high degree of transmissibility, culture should be undertaken only by reference laboratories with biosafety level 3 facilities. If culture is used, either blood or operative specimens of vegetations are acceptable, although the latter will be more sensitive.¹⁸⁹ PCR is also available from reference laboratories; tests on samples from vegetations will be more sensitive than those from blood. A variety of staining techniques can also be used to demonstrate *C. burnetii* in infected tissues.¹⁰²

Differential diagnosis. Because Q fever is not common, routinely searching for it seems impractical, but it is almost certainly underdiagnosed. The acute form of Q fever is essentially self-resolving, and antibody titers do not peak for several weeks after the onset of disease, so diagnostic testing is generally unnecessary. In the correct situation, where there are outbreaks (as occurred in the Netherlands), or for individuals with animal exposure or living in rural areas (particularly with heavy sheep, goat, and cattle farming), *C. burnetii* infection should certainly be considered in the differential. Where the diagnosis becomes critical is in patients with classic fever of unknown origin, for which chronic Q fever should be strongly considered. For patients with known valvular disease or immune compromise, including pregnancy, the possibility of Q fever should be evaluated through the use of serologic screening.

Treatment. Because acute Q fever is generally self-resolving, particularly in children, treatment is usually not necessary. The classic therapy for adults is doxycycline, and alternatives include trimethoprim-sulfamethoxazole, fluoroquinolones, and clarithromycin.¹⁰⁸ The important exception in regard to treatment is the situation of valvular heart disease because 39% of cases of acute Q fever will result in endocarditis in patients with preexisting valvular disease.⁵³ In those cases, the acute treatment should include both doxycycline and hydroxychloroquine.

In contrast to acute disease, chronic Q fever requires prolonged treatment. Eighteen to 36 months of both doxycycline and hydroxychloroquine is recommended.¹⁰⁸ Valve replacement may unfortunately be necessary for cure in cases of endocarditis. Pregnant women should be treated throughout pregnancy with trimethoprim-sulfamethoxazole to prevent transmission and abortion or premature delivery.¹⁴⁰

Prevention. A vaccine for Q fever was developed in Australia for use in people with occupational risks, but it is not available in the United States. Most of the preventive strategies involve minimizing contact with infected animals and postdelivery materials through the rapid and hygienic disposal of placentas and aborted fetuses.¹³⁸

Mycoplasma and Ureaplasma Infections

Natalie M. Quanquin • James D. Cherry

Mycoplasmas and ureaplasmas, the smallest free-living microorganisms, are ubiquitous in nature. More than 100 species have been recovered from many animals, including human beings.^{965,1167,1215,1219} Of this group, 17 have been identified as human pathogens or as part of the normal human flora, with *Mycoplasma pneumoniae* causing respiratory disease as well as a protean array of other clinical manifestations and the genital mycoplasmas (*Mycoplasma hominis*, *Mycoplasma genitalium*, *Ureaplasma urealyticum*, and *Ureaplasma parvum*) having clinical significance in neonates and as sexually transmitted infections (STIs).

These organisms lack a cell wall, giving them the class name Mollicutes, which means “soft skin.”⁵¹⁸ The genera name *Mycoplasma* is derived from Greek and Latin. *Myco* refers to the mycelial, or filamentous, characteristic and *plasma* indicates the plasticity and pleomorphism of the organism.¹¹³⁶ *Urea* in *Ureaplasma* indicates the presence of urease,³⁷⁹ and although this group is in its own genus, because of its shared history, it is commonly included as a “mycoplasma” in the literature.

HISTORY

In 1898, Nocard and Roux⁸⁸⁰ recovered the first *Mycoplasma* organism from cattle with contagious pleuropneumonia. Shortly after the original discovery, many other mycoplasmas were recovered from several different animals.⁴⁶⁶ These other mycoplasmas, which frequently were not associated with disease, originally were called *pleuropneumonia-like organisms*; this designation was abbreviated to PPLO. The term PPLO enjoyed general use until the early 1960s.

The first isolation of a mycoplasma from a human was reported in 1937 by Dienes and Edsall.²⁷³ This organism, now recognized as *M. hominis*, was recovered from an abscessed Bartholin gland. In 1944, Eaton and colleagues²⁹⁹ reported the recovery of an organism, originally called the Eaton agent, from persons ill with primary atypical pneumonia. For many years, the Eaton agent was considered to be a virus even though it was inhibited by streptomycin and chlortetracycline.^{297,298} In 1961, Marmion and Goodburn⁷⁵⁵ noted that the Eaton agent was morphologically similar to PPLOs. In 1962, the organism now known as *M. pneumoniae* was cultivated on a cell-free agar medium and was shown in human volunteer studies to be the etiologic agent of primary atypical pneumonia.^{172,174,466}

In 1954, Shepard¹⁰⁴⁵ reported the recovery of PPLOs with a distinctive small-colony characteristic from men with and without nongonococcal urethritis. These T strains (T for tiny), as they were called, now are classified as *Ureaplasma*. Early literature referred to both ureaplasmas as *U. urealyticum*; however, sequencing techniques have shown sufficient differences that they are now recognized as a separate species—*U. parvum* (formerly biovar 1) and *U. urealyticum* (formerly biovar 2).^{129,177,179} One center that rescreened respiratory and genital samples sent to them over the previous 10 years found that the majority of mollicutes isolated were *Ureaplasma* spp. and that the majority of those sequenced (67%) were actually *U. parvum*.¹⁰⁴⁰

The observation in the 1970s that some men with nongonococcal urethritis and negative cultures still responded to tetracycline led to the closer examination of urethral smears and the discovery of small motile spiral forms that resembled the insect and plant pathogens of the genus *Spiroplasma*. In 1981, this new microbe was classified as *M. genitalium*, and with a 580-kb genome, it has been considered the smallest known organism capable of independent growth and reproduction.^{1141,1142,1167,1170,1171} It served as a guide for the minimal requirements

needed to create a synthetic genome, achieved by John Craig Venter and his team in 2010.⁴⁰¹

CLASSIFICATION

Mycoplasma, *Ureaplasma*, and *Acholeplasma* are genera of the family *Mycoplasmataceae*, in the order *Mycoplasmatales*, which belongs to the class Mollicutes.^{378,965,1215,1219} Both *Mycoplasma* and *Ureaplasma* require cholesterol for growth, have a genome with a molecular weight of approximately 4.5×10^8 , and have nicotinamide adenine dinucleotide (NADH) oxidase localized in the cytoplasm. The limited size of their genomes prevents them from encoding many of the enzymes necessary for amino acid synthesis and energy production, making them slow-growing, fastidious organisms that are difficult to isolate in culture. They generate adenosine triphosphate (ATP) through carbohydrate fermentation (glycolysis), lactate oxidation to pyruvate, and/or arginine hydrolysis, depending on the species.⁵⁸³ Members of the genus *Ureaplasma* are also able to hydrolyze urea.^{1047,1048,1140}

The normal human mollicute flora includes 14 *Mycoplasma*, 2 *Ureaplasma*, and 1 *Acholeplasma* spp.^{161,309,379,693,1154,1167} These organisms are listed by site of most common isolation and frequency of occurrence in Table 196.1. Most species do not invade submucosal tissues and do not cause disease in immunocompetent hosts unless this protective barrier is breached through surgery or trauma. *Mycoplasma salivarium* and *Mycoplasma orale* are commonly part of the normal respiratory flora and have not been associated with illness in nonimmunocompromised persons. *M. hominis*, *U. urealyticum*, and *U. parvum* also are recovered commonly from human genital tracts, and although they are considered normal flora, they can trigger inflammatory processes in pregnant women which have been linked to preterm labor. *M. genitalium* is also found in the genital tracts of sexually active individuals and is a cause of nongonococcal urethritis. Inflammatory processes resulting from the presence of *M. genitalium* and *Mycoplasma fermentans*, another colonizer of the genital tract, are possible; however, a link with adverse pregnancy outcomes has not been definitively established.^{655,1137,1215,1217} Persistent infections in blood, bones, joints, and kidneys with *Mycoplasma penetrans*, *Mycoplasma pirum*, *M. fermentans*, *M. hominis*, and *U. urealyticum* have occurred in patients with immunodeficiencies (Tully JG. Personal communication. December 1, 1991).^{67,817} *Mycoplasma buccale*, *Mycoplasma amphoriforme*, *Mycoplasma primatum*, *Acholeplasma laidlawii*, and *Mycoplasma lipophilum* are rarely isolated and are not thought to cause disease in nonimmunocompromised humans. *Mycoplasma faucium* has been rarely identified in brain abscesses caused by polymicrobial infections likely originating from the oropharynx, but its contribution to the infection is unclear.³⁰³ *M. pneumoniae* is a common cause of respiratory and other human illness.

MYCOPLASMA PNEUMONIAE

Properties

Morphology

Because mycoplasmas lack a cell wall, they all tend to be pleomorphic. Kammer and colleagues⁵⁶⁸ studied the morphologic characteristics of *M. pneumoniae* organisms grown in broth medium by scanning electron microscopy and grouped their observations by days of incubation. From 0.3 to 2 days, the predominant morphologic feature consisted of 0.51 ± 0.011 μm symmetric round forms in tightly packed clusters. During the

interval from day 2 to day 6, branched and straight filaments and bulbs were the predominant forms. The bulbous elements had a diameter of $0.25 \pm 0.006 \mu\text{m}$, and the filamentous forms were $0.19 \pm 0.005 \mu\text{m}$ in diameter. The filaments were intertwined, and occasional round forms were observed. From day 6 to day 10, the organisms had a rounded shape but were asymmetric. Their diameter was $0.72 \pm 0.027 \mu\text{m}$, and they occurred in groups of three or four cells. Biberfeld and Biberfeld⁸³ noted that *M. pneumoniae* filamentous forms varied in length from 1 to 5 μm .

The ultrastructure of *M. pneumoniae*, as well as that of all members of the family *Mycoplasmataceae*, is relatively simple and consists of a cell membrane and cytoplasm.^{379,1166} In 7-day *M. pneumoniae* cultures, Domermuth and associates²⁷⁷ noted the following characteristics: elementary bodies 105 to 120 nm in diameter, mature cells with a maximal diameter of 690 to 750 nm and an average diameter of 440 to 590 nm, asymmetry of the limiting membrane, electron-dense lines outside the limiting membrane, and dense bodies as cytoplasmic inclusions.

Wilson and Collier¹²⁵⁵ studied the ultrastructure of *M. pneumoniae* in hamster tracheal organ culture and noted filamentous organisms with three-layered membranes. The cells were polymorphic but each had a specialized terminal structure at the site of attachment to the organ culture. This terminal structure had a dense central core containing a denser central filament. Between the organism and the organ culture cell, fusion was not detected, but a loose network of fibrils was noted between the two surfaces. The bodies of the mycoplasmas contained densely stained fibrillar material and cytoplasmic granules, both of which contained nucleic acid.

Motility and Multiplication

Bredt¹¹⁶ studied *M. pneumoniae* motility and multiplication on a glass surface in liquid medium by phase-contrast microscopy. The organisms were observed to multiply by binary fission; first, short filamentous structures were formed, which then separated into two cells. A growth cycle between two separations lasted approximately 3 hours. After division, the new cells moved by means of a gliding motion. The gliding speed has been noted to be approximately 0.2 to 0.5 $\mu\text{m/s}$, but maximal speeds of 1.5 to 2.0 $\mu\text{m/s}$ have been observed.⁹⁵⁷

Composition

Mycoplasmas are composed of approximately 40% to 60% protein, 10% to 20% lipid, and a variable amount of carbohydrate. The *M.*

pneumoniae genome is circular, double-stranded DNA with a contour length of $4.8 \times 10^8 \text{ D}$ and a size of 816 kb.⁸²⁵ The guanosine plus cytosine content of the DNA is 38.6% to 40.8%.^{108,863,965,1139}

Growth Characteristics and Physical Properties

M. pneumoniae grows in mycoplasma broth medium and on agar enriched with yeast extract and animal serum.^{169,466,965,1136,1166} *M. pneumoniae* ferments carbohydrates and requires sterol for growth. It grows under both anaerobic and aerobic conditions, but growth is more consistent when it is incubated in nitrogen and 5% carbon dioxide. When compared with other mycoplasmas isolated from humans, *M. pneumoniae* grows relatively slowly, with visible formation of colonies rarely occurring in less than 1 week and possibly taking 3 weeks or more. Repeated agar passage results in more rapid growth, and laboratory strains thus treated produce colonies in 3 days.

M. pneumoniae colonies on agar generally appear different from the classic mycoplasma “fried egg” look noted with other types recovered from humans. The *M. pneumoniae* colony is spherical and dense, with a rough “mulberry” surface.

M. pneumoniae has the following enzyme systems: NADH₂ oxidase, nicotinamide adenine dinucleotide phosphate (NADPH₂) oxidase, lactate dehydrogenase, probably succinic dehydrogenase, and diaphorases.⁴⁶⁶ In liquid medium, the following can be noted: acid color change in medium with added glucose and phenol red as a result of glucose metabolism, reduction of methylene blue in medium as a result of dehydrogenase activity, and reduction of 2-3-5 tetrazolium chloride to red formazan by dehydrogenase activity.¹¹³⁶

On agar, *M. pneumoniae* hemolyzes erythrocytes in an agar overlay by liberation of peroxide. Erythrocytes and other cells adsorb to *M. pneumoniae* colonies, and organisms in suspension cause hemagglutination. *M. pneumoniae* has also been found to create biofilms on abiotic surfaces,⁶²² which may help it survive in the environment.

Mycoplasmas, including *M. pneumoniae*, are heat sensitive. They have a half-life of less than 2 min at 50°C (122°F) and lose viability within 1 week at room temperature.¹¹⁶⁶ They can be stored for several years at –20°C (–4°F), but –70°C (–94°F) is optimal for long-term storage.

Mycoplasmas are resistant to osmotic environmental changes but are sensitive to detergents. They are inhibited by gold salts and antibiotics not directed against cell wall synthesis.

Antigenic Composition

The following immunologic reactions have been noted in association with *M. pneumoniae*–host serum interactions: specific complement fixation; precipitation in gel; growth inhibition; indirect hemagglutination; metabolic inhibition; antigen–antibody union identified by immunofluorescence, enzyme-linked immunosorbent assay (ELISA), and radioimmunoassay; adherence inhibition assay; and nonspecific complement fixation (i.e., positive serologic test result for syphilis) and agglutination (i.e., cold and *Streptococcus* MG agglutinins).^{135,506,533,693,949,1136}

M. pneumoniae organisms have both membrane and cytoplasmic antigens.^{338,589} Two membrane antigens can be identified by immunodiffusion,⁹³⁸ with the major membrane antigen being found in the lipid fraction of the organism.^{338,589} The antigens are glycolipids and are of major importance in complement fixation, metabolic inhibition, and mycoplasmacidal reactions.¹⁴⁶ The cytoplasmic (soluble) antigen, which also contains lipid, can be identified by complement fixation when the antigen is prepared by phenol extraction. Many surface lipoproteins are also differentially expressed on contact with epithelial cells⁴⁵⁰ and are thought to play a role in both activating and evading the innate immune system.^{124,519}

Humans have an immunoglobulin (Ig) G immune response to eight principal protein antigens.^{15,108,177,251,252,377,631,641,1203,291} These eight polypeptides have the following molecular masses: 170, 130, 116, 90, 68, 45, 35, and 30 kDa. The 170-kDa antigen is the P1 protein. This protein is localized at the surface of the terminal organelle (terminal structure), is the major adhesin responsible for attachment, and is the cause of the gliding motility of the organism. Antibodies to P1 protein inhibit hemadsorption and adherence to respiratory epithelium.^{502,504,505,532,564,632,1107} Other important adhesins include the 30-kDa protein (P30) and 116-kDa protein (P116). In addition, multiple accessory proteins are involved

in the adherence of *M. pneumoniae* to host cells,⁹⁶⁵ including P65, HMW1, HMW2, HMW3, and A, B, and C.^{58,461}

The 68-kDa community-acquired respiratory distress syndrome (CARDS) toxin is a recently identified protein unique to *M. pneumoniae* but that shares some homology with pertussis toxin.^{570,787} It possesses adenosine diphosphate (ADP) ribosyltransferase activity, is highly immunogenic, and has been associated with airway cellular damage.^{72,106,571,787} Diagnostic assays based on this protein have recently been developed.⁸³³

M. pneumoniae strains can be divided into two groups based on the sequence variation in the P1 gene.^{281,282,292} Within this classification system (types 1 and 2), multiple variant subtypes also exist, which can be distinguished by restriction fragment length polymorphism (RFLP)¹⁰⁹¹ or polymerase chain reaction (PCR)-based denaturing gradient gel electrophoresis.¹²⁶⁶ Type 2 strains have been found to produce higher levels of CARDS toxin⁷⁰⁹ and stronger biofilms¹⁰⁶⁴; however, studies have not yet shown an association between strain type and worse clinical pathology.⁸⁷³ Further molecular typing of strains by the number and location of tandem repeats in the gene is also possible and mostly used for epidemiologic tracking, although there is some disagreement regarding the classification system.¹¹¹⁵ Three prevalent "multilocus variable-number tandem-repeat analysis" types in recent years are 4-5-7-2, 3-5-6-2, and 3-6-6-2,²⁷⁰ and one study in Hong Kong found that increasing macrolide resistance rates in *M. pneumoniae* were predominantly a result of mutations in 4-5-7-2, from 25% in 2011 to 59.1% in 2012, to 89.7% in 2013, and to 100% in 2014.^{480,953}

Membrane determinants of *M. pneumoniae* cross-react with the erythrocyte glycoprotein containing the I antigen and the related sugar chain (F1)^{474,537}; with pneumococcal serotypes 23 and 32¹⁷; with the glycolipids of spinach, parsnips, and carrots; with selected strains of *Staphylococcus aureus* and group A streptococci; and perhaps with the filamentous hemagglutinin of *Bordetella pertussis*.^{432,527,590,1194}

Animal Susceptibility

M. pneumoniae grows and causes pneumonia in hamsters and cotton rats and causes inapparent infection of the bronchial epithelium of chicken embryos.⁹⁴⁹

Epidemiology

Epidemic Pattern

In large urban areas, *M. pneumoniae* is endemic; infection and disease occur throughout the year. Foy and associates^{359,364} noted cultural or serologic evidence of *M. pneumoniae* infection in a Seattle, Washington prepaid medical care group during all seasons throughout an 11-year period. Similar endemicity has been reported in other studies.^{816,821,879} Wan and colleagues¹²²² tested air filters at a hospital in Taiwan and detected seasonal peaks of *M. pneumoniae* in the pediatric emergency department (July) and outpatient areas (August–January). In addition to the background endemic pattern, *M. pneumoniae* enjoys a cyclic epidemic pattern that is specific for a particular urban community. Epidemics have occurred at 3- to 7-year intervals,^{321,364,560,696,879} most recently in Europe and Jerusalem from 2010 to 2012.^{165,305,679,874,1176} Epidemics, which develop slowly, usually start in the fall and persist in the community for 12 to 30 months. While previous epidemics were thought to represent shifts in circulating P1 strain types,^{591,904} there are conflicting reports regarding whether this most recent epidemic also saw a change in the pattern. Analysis of respiratory samples from *M. pneumoniae*-infected patients in Germany from 2003 to 2012 showed that 55% of strains were type 2, with no type shifts preceding or during the epidemic.⁵²⁹ However, two towns in western Russia experienced *M. pneumoniae* outbreaks in 2013 solely with the type 2c strain, whereas samples from that region taken in 2006 to 2007 and 2010 showed that 41% were type 1, 52% were type 2a, and only 7% were type 2c.³⁰² Similarly, samples taken from patients in China showed that 20% were type 2 between 2008 to 2012, which increased to over 40% in 2013 and 2014.¹²⁹⁵ A retrospective analysis of 199 cases in the United States showed a similar pattern, with type 1 strains being predominant from 2006 to 2011, after which type 2 and variant strains each increased between 2011 and 2013.²⁷⁰

As part of an influenza surveillance program, Layani-Milon and associates⁶⁶⁰ studied acute respiratory infections in outpatients for six

winters in the Rhône-Alpes region of France by PCR plus a hybridization-based detection system. Each year from 1992 to 1997, at least one peak of *M. pneumoniae* infection was noted in the late fall. Overall, they studied 3897 children and adults with acute respiratory illnesses, and 7.3% were found to be infected with *M. pneumoniae*. The yearly rate of *M. pneumoniae* cases fell from 10.1% in 1992 to 1993 to 2.0% in 1995 to 1996; in the subsequent year (1996–97), it rose to 4.2%.

Incidence of Infection and Disease

In the past, most pediatricians and other physicians considered *M. pneumoniae* illness to be uncommon in the general population. The initial epidemiologic studies were concerned mainly with the occurrence of pneumonia in closed populations, such as the military and boarding schools.^{173,816,997,1104,1106,1185} During the past 52 years, however, many large studies in civilian populations, coupled with more sensitive diagnostic techniques, have indicated that both infection and disease with *M. pneumoniae* occur commonly.*

Hornsleth⁴⁹⁵ examined 367 serum samples collected from children hospitalized in Copenhagen from September 1963 to May 1965 for complement-fixing antibodies. He noted that 42% of infants 6 to 11 months of age had demonstrable antibody; from 1 to 9 years of age, more than two-thirds of the children had antibody. Suhs and Feldman¹¹¹³ found a similar high prevalence of hemagglutination-inhibiting antibody in the sera of residents of Point Barrow, Alaska, but only 5% of the serum samples from a children's home in Syracuse had measurable antibody. A study of 319 pediatric patients with chronic respiratory disease found that 32.6% had bronchoalveolar lavage fluid positive for mycoplasmas, of which only 31% represented *M. pneumoniae*.⁹²⁴ Brunner and associates¹²⁸ detected serum antibody by the sensitive radioimmunoprecipitation test in 28% of 7- to 12-month-old infants, 55% of 13- to 24-month-old children, 67% of 25- to 60-month-old children, and 97% of persons older than 17 years. The high antibody prevalence noted in this study and the findings in Copenhagen and Alaska suggest an infection incidence rate of approximately 20% to 30% per year in a susceptible population of young children. The prevalent antibody noted at an early age in these studies possibly is not caused specifically by *M. pneumoniae* infection but instead could be the result of exposure to the many cross-reacting antigens in nature.^{17,399,590} However, studies by Fernald and colleagues,³⁴⁰ in which infants and children in a daycare center were monitored systematically, indicated a yearly infection rate of approximately 12%.

Monto and colleagues,⁸²¹ in a large study involving 3243 persons, investigated the incidence of infection in six yearly cohort groups of children and adults. Infection was determined by significant rises in titer of complement-fixing antibody on three serum specimens collected during a 1-year period from each subject. The overall yearly infection rate was found to be 5.3%. The highest rate (8.8%) occurred in the 5- to 9-year-old group. Infants younger than 1 year had a rate of 2.8%.

Brunner and associates¹²⁸ noted that geometric mean antibody titers tended to increase with increasing age, which suggested that the older children were being reinfecting. Fernald and colleagues³⁴⁰ reported that 5 of 22 children infected with *M. pneumoniae* in their investigation experienced reinfections during the 5-year observation period. In the study by Monto and associates,⁸²¹ 24.4% of the 172 infections detected in subjects of all ages were reinfections. During a 12-year serologic surveillance period, Foy and coworkers³⁶⁴ noted great variation in the incidence of *M. pneumoniae* infection; in the period from October 1965 to May 1966, only 0.2% of 398 children had fourfold rises in complement-fixation antibody titer, whereas during the May 1973 to May 1974 period, 35% of 246 subjects 10 to 20 years of age had serologic evidence of infection.

The incidence of disease caused by *M. pneumoniae* depends on the endemic or epidemic prevalence of the organism in the community and is age related. The incidence of *M. pneumoniae* by age for two epidemics and the surrounding endemic periods in Seattle was studied by Foy and associates.³⁶⁴ The highest epidemic attack rate was 14 per

*References 51, 52, 87, 128, 154, 233, 269, 278, 287, 309, 318, 340, 363, 360, 361, 362, 364, 367, 369, 412, 416, 429, 495, 540, 549, 560, 696, 707, 715, 801, 821, 822, 870, 879, 910, 1044, 1113, 1165.

1000 children 5 to 9 years of age, and the highest endemic attack rate (4 per 1000) occurred in the same age group. Children 10 to 14 years of age had the second highest attack rate during both epidemic and endemic periods. The attack rate in children younger than 5 years was about twice that observed in young adults.

The ratio of symptomatic to asymptomatic infection has varied across studies. In family studies, both Balassanian and Robbins⁵⁷ and Foy and associates³⁶³ noted that only 15% of infections were asymptomatic, whereas Saliba and associates⁹⁹⁷ noted that 55% of the residents of a boys' home had asymptomatic infection. Chanock and colleagues¹⁷³ observed that only 1 in 30 infections in Marine recruits manifested as clinically apparent pneumonia. Recent studies on the human microbiome show that the presence of *M. pneumoniae* in the airway is more common than previously thought, although it is unclear how much represents acute versus chronic infection, reinfection, or asymptomatic carriage.⁴⁵ A study in the Netherlands found *M. pneumoniae* DNA in 21% of 405 asymptomatic children and 16.2% of children with upper respiratory symptoms, the latter persisting for up to 4 months after sampling.¹⁰⁸⁹

Incubation Period

The reported incubation period has varied from a mean of approximately 1 week in volunteer studies and point-source epidemics to 3 weeks in community outbreaks.* In a volunteer study, Rifkind and colleagues⁹⁷⁰ administered tissue culture-grown *M. pneumoniae* in a concentration of 320 to 1280 EID₅₀ (mean egg-infective dose) into the nose and posterior pharyngeal area of 27 men with no demonstrable antibody. In this study, pneumonia occurred 9 to 12 days after inoculation, following 1 to 3 days of upper respiratory tract illness. In six volunteers, only upper respiratory tract illness was noted, and the incubation period varied from 4 to 9 days. In a similar study in which volunteers received 10⁶ to 10⁷ broth-grown organisms, the incubation period was 8 to 10 days.¹⁰⁷³

In an interesting common-source outbreak caused by an intense 8-hour exposure at a party, the peak incubation period was 13 days and most of the cases occurred between days 11 and 14.³²⁴ In another probable point-source outbreak, which may have resulted from a room aerosol, the incubation period varied from 4 to 9 days.¹⁰⁰⁵ In studies of case-to-case intervals in families, Foy and associates³⁶³ reported a median incubation time of 23 days, with most of the cases occurring between days 16 and 25. In similar studies, Copps and colleagues²³³ noted an average interval of 21 days, and Biberfeld and Sterner⁸⁷ found a modal value of 20 days. A point-source outbreak in a family unit was described in which all seven family members became ill 10 to 16 days after the onset of symptoms in the index case.⁵⁹⁶

The longer incubation period in the family situation than in the volunteer studies and the point-source outbreaks may be the result of larger inocula in the last instances. In contrast to other respiratory illnesses, such as measles and influenza, the spread of disease caused by *M. pneumoniae* in both closed populations (such as military training units and boarding schools) and open communities is usually slow. For example, the introduction of influenza or measles into a family most often results in infection of all susceptible persons from the primary case. In contrast, the spread of *M. pneumoniae* through a family of six people probably would require three or four passages. Foy and associates³⁶³ noted secondary attack rates in families of 64% for children and 17% for adults. Biberfeld and Sterner⁸⁷ reported secondary infection rates of 41% and 84%, respectively, for adults and children in families. In contrast to family groups, the spread of *M. pneumoniae* in schools and other situations of brief exposure is low.^{360,368} In one Seattle elementary school, the infection rate was 18%. Foy and Alexander³⁵⁹ believe that neighborhood spread among playmates is more important than school exposure in community transmission of *M. pneumoniae*.

Transmission in families occurs during the acute phase of illness; transmission by persons with asymptomatic infection has not been documented.³⁶⁰

Geography

The endemic and epidemic presence of *M. pneumoniae* has been demonstrated in the urban areas of developed countries with temperate

climates throughout the world.* Serologic investigations in more remote areas, including both arctic and tropical zones, also indicate the presence of *M. pneumoniae* infection. Suhs and Feldman¹¹¹³ found measurable antibody in the serum of 68% of 169 persons in Point Barrow, and Golubjatnikov and associates,⁴¹⁶ in a study of children in a remote Mexican highland community, detected seropositivity in 16% of 637 children. Serologic evidence of infection also has been noted in Cairo, Singapore, Hong Kong, the West Indies, and southern Africa.^{170,560} Incidence studies have not been performed in rural areas, but patterns of infection probably would be characterized by epidemic periods of a year or so and then complete absence of *M. pneumoniae* circulation for several years.

Gender Difference

Although the results of studies have varied, the difference in the incidence of *M. pneumoniae* disease by sex is small. During the 11 years of study in Seattle, Foy and associates³⁶⁴ noted that the rate of *M. pneumoniae* pneumonia was higher in women than in men in the 30- to 39-year age group (1.8 vs. 1.2 per 1000). In infants, boys were afflicted more often than girls; otherwise, the rates for children by gender were virtually identical. Jensen and associates⁵⁴⁹ found that pneumonia, otitis media, and nasopharyngitis in various combinations occurred more commonly in boys than in girls. Monto and colleagues⁸²¹ noted that boys younger than 5 years of age had more infections, but that the reverse was true for children 5 to 14 years of age. In a review of Japan's National Surveillance Data, Eshima and colleagues³¹⁷ found a slightly greater female preponderance in symptomatic infection at all ages except those over 70 years old. In other studies involving all age groups, males have shown a slightly greater frequency of illness than females.^{754,879} In the Seattle family studies, symptoms were more severe in boys than in girls.

Pathogenesis and Pathology

Sequence of Events in Infection

M. pneumoniae infection is acquired via the respiratory route from the respiratory secretions of an ill person infected with this agent. Spread can be accomplished by small-particle aerosols or large droplets of secretions coming in contact with the epithelial surface of the nasopharynx and perhaps the surfaces of the lower respiratory tract (i.e., trachea, bronchi, and bronchioles) as well. In volunteer studies, Couch²³⁸ observed that the 50% human infectious dose by small-particle aerosol was 1 colony-forming unit (nasal instillation required a dose that was 100 times greater).

Because epidemiologic data indicate the need for close and perhaps prolonged personal contact for transmission of infection, transmission by small-particle aerosol probably occurs rarely under natural conditions. After acquisition of the infectious agent, multiplication occurs extracellularly on mucous membrane surfaces. The incubation period, which varies from 4 days to more than 3 weeks, probably depends strongly on the size of the original inoculum. The extent of the respiratory infection increases during the incubation period, and shedding of organisms in respiratory secretions can be observed 2 to 8 days before clinical illness.²³⁸ Initial symptoms of infection include headache, malaise, fever, sore throat, and cough; evidence of lower respiratory tract disease is present within the succeeding 3 days.^{269,970} The method of extension of infection within the respiratory tract is unknown. The extent of disease possibly depends totally on the initial distribution of the infectious agent at the time of acquisition rather than on spread of infection from a primary upper respiratory site.

After the onset of clinical symptoms, the concentration of *M. pneumoniae* in respiratory secretions peaks, remains high for approximately 1 week, and then persists for 4 to 6 weeks or longer.^{238,269} The associated symptoms and signs in disease caused by *M. pneumoniae* (i.e., meningitis, arthritis, hemolytic anemia, rash, and pericarditis) suggest the possibility of frequent dissemination of the organism from the respiratory tract. Some reviews on the subject tend to discount the possibility of generalized *M. pneumoniae* infection and attribute the associated systemic clinical findings to immunologic events related to respiratory infection.^{238,269,796} However, little published evidence indicates

*References 87, 233, 324, 363, 360, 366, 970, 1005, 1074, 1167.

*References 89, 269, 333, 360, 364, 540, 696, 732, 754, 849, 879, 1097.

that the organism has been sought carefully in the blood and other sites of dissemination. In many instances, *M. pneumoniae* has been recovered from or identified by PCR in the blood, pericardial fluid, middle ear fluid, vesicular skin lesions, pleural fluid, kidneys, brain, and cerebrospinal fluid (CSF).^{*} In addition, the observation of low CSF glucose in *M. pneumoniae* meningoencephalitis suggests direct involvement by the organism.⁶¹²

Pathology

Pathologic findings in *M. pneumoniae* disease in children have not been reported, and only minimal data from adults are available. However, a reasonable understanding of the pathologic process of *M. pneumoniae* disease can be constructed from studies in the hamster, various tracheal organ cultures, and human biopsy and postmortem material.[†] The primary damage in *M. pneumoniae* infection is to the epithelial lining of the mucosal surfaces of the respiratory tract. This damage has been observed on the surface of bronchi, bronchioles, and alveoli; clinical symptoms in children suggest that similar pathologic changes occur in the trachea and upper respiratory tract as well. Specifically conspicuous is destruction of the ciliated epithelium of the bronchi and bronchioles. Because of mucosal desquamation and ulceration, the lumina contain considerable debris; added to this debris is an inflammatory exudate consisting of fibrin, mononuclear cells, and neutrophils. The alveolar spaces contain similar exudate and edema fluid.

The walls of the bronchi and bronchioles are thickened by edema and contain an infiltrate of macrophages, lymphocytes, and plasma cells. The alveolar walls are also thickened and contain lymphocytes, mononuclear cells, and erythrocytes. Dilatation of the septal capillaries occurs. Edema and cellular infiltration extend into the interstitial spaces. Gross examination of the lungs reveals areas of hemorrhage and congestion. The pleura may contain patches of fibrinous exudate, and pleural fluid may be present. The pneumonic areas may be discrete or widespread.

A biopsy specimen of a vesiculopustular skin lesion revealed an epidermis with mild acanthosis and marked edema that primarily was intracellular.¹¹⁴⁶ The papillary and upper reticular dermis contained neutrophils and round cells, and hemorrhagic foci were present within the upper corium and epidermis. The blister fluid contained plasma protein and neutrophils. Findings in other organs include mesenteric lymphadenitis, focal hepatic necrosis, follicular splenitis, acute myocarditis, and hemorrhagic encephalitis.

Immunologic Events

Specific antibody. A specific serum antibody response usually occurs after infection with *M. pneumoniae*, which can be measured by many different serologic techniques: immunofluorescence, complement fixation, indirect hemagglutination, precipitation, growth inhibition, mycoplasma-macidal antibody test, ELISA, radioimmunoassay, adherence inhibition assay, and radioimmunoprecipitation test.[‡]

Complement-fixing antibodies occur early in *M. pneumoniae* disease, reach a peak titer in approximately 1 month, and then decline slowly over a variable period. Fluorescent-staining antibodies and antibody determined by ELISA have temporal patterns similar to those of complement-fixing antibodies. Growth-inhibiting antibodies appear later (i.e., 2–3 weeks after the onset of illness), peak later, and persist longer than do complement-fixing antibodies. The initial serum immune response includes specific IgM, IgG, and IgA antibodies. After clinical illness and convalescence, specific antibody is located mainly in the IgG serum fraction. Occasionally, significant levels of IgM antibody persist for several months or years after infection.^{82,129,312,557} Antibody titer responses in infected children are generally of a lesser magnitude than those in adults.²⁸⁷ Asymptomatic infections in children may not be associated with a measurable serum antibody response. *M. pneumoniae*-specific IgE antibodies have been detected in the sera of patients with asthma, atopic dermatitis, or both conditions.¹¹⁵⁷

After infection, specific antibody is also present in nasal secretions and sputum.^{81,126} In volunteer studies, Brunner and colleagues¹²⁶ noted that 42% and 73% of subjects had IgA nasal and sputum responses, respectively. Biberfeld and Sterner⁸⁸ found specific antibody in 44 of 55 sputum specimens from patients with *M. pneumoniae* infection of the lower respiratory tract. They noted IgA antibody in all specimens tested, IgG antibody in 24 of 31 specimens, and IgM antibody in 13 of 27 specimens.

Specific cell-mediated immunity. Fernald and coworkers^{336,337} demonstrated that lymphocytes from adults previously infected with *M. pneumoniae* undergo blast transformation when cultured in vitro in the presence of *M. pneumoniae* organisms. In age-related studies, researchers noted that only one of nine children younger than 4 years of age with documented previous infection had evidence of specific cell-mediated immunity as measured by lymphocyte stimulation.³⁴⁰ In contrast, 7 of 12 children older than 4 years and 87% of an adult group demonstrated specific lymphocyte stimulation. This study suggests that specific cell-mediated immunity increases as a function of age and depends on repeated infection. Koh and colleagues⁶¹⁴ noted high levels of interleukin (IL)-4 and a high IL-4/interferon (IFN)- γ ratio in the bronchoalveolar lavage fluid of children with *M. pneumoniae* pneumonia, thus suggesting a predominant T_H2-like cytokine response. Wang and coworkers¹²²⁶ found elevated IL-4 and decreased IL-2 levels in children infected with *M. pneumoniae*, and found that those with a particular IL-2 polymorphism had an increased risk of asthma and of a higher load of the pathogen. Martin and colleagues⁷⁵⁷ found that leukocytes from volunteers with *M. pneumoniae* infection demonstrated chemotaxis in the presence of the organism, whereas leukocytes collected before infection did not. Patients infected with *M. pneumoniae* also respond with IFN- γ in their blood and nasopharyngeal secretions early in infection and with IFN- γ during convalescence.^{850,851}

Nonspecific responses. Antibodies to several diverse antigens develop during human infection with *M. pneumoniae*. The best known of these antibodies are cold agglutinins, which are useful in the diagnosis of *M. pneumoniae* pneumonia.^{236,330,467,540,1076} Cold agglutinins are directed against the I antigen of erythrocytes.^{537,697,1076} Most pneumonias in which serum cold agglutinins are noted are caused by *M. pneumoniae*. Cold agglutinins are detected in the serum of approximately 75% of patients with *M. pneumoniae* pneumonia; they are less common in *M. pneumoniae* infection without pneumonia.¹⁶⁹

Patients with *M. pneumoniae* also frequently develop antibodies to the MG strain of nonhemolytic streptococci⁶⁹⁵ and occasionally to *M. genitalium*,⁶⁹⁹ *M. hominis*,¹⁰⁰⁹ *M. salivarium*, *Mycoplasma hyorhinis*, *Mycoplasma orale*, *Mycoplasma pulmonis*, and *Mycoplasma mycoides* variety *mycoides*, the etiologic agent of contagious pleuropneumonia of cattle.⁶⁷⁸ Cross-reacting antibodies to filamentous hemagglutinin and pertactin of *B. pertussis* also occur.¹¹⁹⁴ Other heterologous antibodies found in the serum of patients with *M. pneumoniae* infection include those to smooth muscle, the mitotic spindle apparatus, brain, lung, liver, and Wasserman (WR) cardiolipin antigen.^{81,89,698} In addition to these findings, Biberfeld and Norberg⁸⁵ detected immune complexes by the platelet aggregation technique in the sera of 16 of 39 patients with acute respiratory illness caused by *M. pneumoniae*. Mizutani⁸¹¹ demonstrated the presence of circulating immune complexes in most patients with pneumonia caused by *M. pneumoniae*. The same investigator also detected rheumatoid factor in the sera of patients with *M. pneumoniae* disease.⁸¹²

Possible Mechanisms of Disease Production

Numerous studies have been performed in an attempt to understand the pathogenesis of respiratory disease caused by mycoplasmas.^{128,192,193,191,219,217,218,225,227–230} Of particular interest in human *M. pneumoniae* infection is the apparent high prevalence of infection in infants, children, adolescents, and young adults, but the frequently mild nature of disease in infants and young children in comparison with older patients. Some studies suggest that the more severe disease in older patients is associated with reinfection and is mediated somewhat by immunologic responses.^{1008,1114}

Organ culture and animal studies indicate that damage at the site of primary infection—the respiratory epithelium—is the result of close

*References 2, 26, 68, 75, 93, 262, 353, 514, 574, 617, 657, 719, 720, 727, 844, 845, 848, 859, 860, 965, 1080, 1082, 1121, 1158.

†References 280, 514, 561, 617, 657, 735, 802, 920, 1146, 1304.

‡References 127, 128, 135, 286, 339, 467, 506, 533, 693, 705, 949, 1022, 1144.

organism–cell attachment.^{191,228,230,503,701,702,840,943} This attachment of organism to cell uses neuraminic acid receptors on the cell.¹⁰⁸¹ In an organ culture system with *M. mycoides* variety capri, ciliary damage was decreased when the cellular receptor sites were treated with receptor-destroying enzyme.¹⁹¹ Lipman and associates^{701,702} noted that one attenuated *M. pneumoniae* strain had lost its ability to cytoadsorb. The close association of organism and cell allows the transport of specific damaging material to the cell. Although the precise nature of this substance is not known, the data available suggest that it might be hydrogen peroxide. It is liberated by *M. pneumoniae* in vitro; in organ culture studies, hydrogen peroxide has been shown to be the damaging factor in another *Mycoplasma* infection.^{191,702,704} In cell culture, *M. pneumoniae* inhibits host–cell catalase activity.²⁰ This inhibition of catalase activity enhances the toxicity of the hydrogen peroxide generated by the microorganism. *M. pneumoniae* also enters host cells and persists intracellularly for at least 7 days.⁶⁵

Once released in the cell, the CARDS toxin is able to mediate mono-ADP ribosylation and vacuolization, processes that lead to airway inflammation and damage to ciliated respiratory epithelial cells.^{106,570,635,787} Another possible important component of *M. pneumoniae* pathogenicity is the induction of proinflammatory and other cytokines during infection.^{444,455,643,1036,1054,1224,1273}

In addition to direct damage from inflammatory cytokines and bacterial cytotoxins, other mechanisms have been proposed in the development of extrapulmonary findings in *M. pneumoniae* infection.^{856,1206} Autoantibodies are often detected in these cases, most likely as a result of cross-reactivity between host cell proteins and mycoplasma membrane antigens. Autoimmune mechanisms have been linked to findings as varied as arthritis, coagulopathies, and encephalitis in *M. pneumoniae* infection. Another mechanism of pathology commonly seen is vascular occlusion caused by either direct inflammation of the vessels or various coagulopathies associated with *M. pneumoniae* infection. This led to associated findings, such as stroke, pulmonary emboli, and coronary artery disease.^{198,210,352,387,602,665,681} Although not directly proven, the ability of mycoplasma to bind to erythrocytes and disseminate through the bloodstream may contribute to the high frequency of extrapulmonary findings seen with these infections.⁸⁶⁴

Fernald and associates³⁴⁰ noted that specific cell-mediated immunity to *M. pneumoniae* as measured by lymphocyte transformation becomes more prevalent with increasing age, as does specific antibody. Their studies suggest that more than one exposure to antigen may be necessary to elicit both humoral and cellular responses. Fernald and Glezen,³⁴¹ in an inactivated *M. pneumoniae* vaccine trial in children, noted that lymphocyte sensitivity developed in many recipients but not a humoral antibody response. In a trial of an inactivated vaccine in adults, Smith and associates¹⁰⁷³ found that on challenge infection, an exaggerated illness occurred in vaccinees who failed to form humoral antibodies after immunization. These findings have led to the consideration that persistent specific cell-mediated responsiveness might contribute to the pulmonary process in *M. pneumoniae* infection. However, the incubation period of illness in adults and children is similar, which argues against the sensitization theory.²¹³

Foy and associates³⁶⁵ noted that complement-fixing antibodies remained elevated for 2 to 9 years after infection with pneumonia but fell quickly after the second year in persons with mild illness. Protection against reinfection was better in those who previously had pneumonia than in those with mild symptoms.

Clinical Manifestations

Pneumonia

Pneumonia is the most important clinical manifestation of *M. pneumoniae* infection, and this agent is responsible for 10% to 20% of all cases of pneumonia.* The highest incidence of pneumonia caused by *M. pneumoniae* in Seattle occurred in children 5 to 14 years of age.³⁶⁴ In a study in Chiba Prefecture, Japan, researchers noted that the peak age of lower respiratory tract illness caused by *M. pneumoniae* was

4 years.⁸⁴⁶ In a prospective study of community-acquired pneumonia in Finland, 11% of the children with *M. pneumoniae* infection were younger than 5 years of age, 32% were between 5 and 9 years of age, and 57% were 10 to 14 years of age.⁴⁷¹ Although researchers frequently state that *M. pneumoniae* pneumonia rarely occurs in children younger than 5 years of age, in actuality, the incidence in this group was found to be about twice that noted in young adults in Seattle.³⁶⁴ Pneumonia caused by *M. pneumoniae* occurs less commonly in children younger than 2 years of age and rarely in infants younger than 6 months of age. The apparent frequency of *M. pneumoniae* pneumonia is influenced by the relative occurrence of pneumonia caused by other pathogens. During the child's first 5 years of life, *M. pneumoniae* is only one of many agents (e.g., respiratory syncytial virus, adenoviruses, parainfluenza viruses, influenza viruses, *Streptococcus pneumoniae*, and *Haemophilus influenzae*) that cause pneumonia. During later childhood and adolescence, pneumonia as a consequence of infection with these other agents is a rare event; therefore *M. pneumoniae* is the leading cause of pneumonia in these persons.

Because isolation rates of *M. pneumoniae* during both endemic and epidemic periods do not vary greatly by season, as do those of common respiratory viruses, the proportion of patients with *M. pneumoniae* pneumonia increases during the summer months.

Symptoms and signs. Since 1961, a large number of studies have reported the frequency of signs and symptoms in *M. pneumoniae* infection.* Unfortunately, many studies have included only special populations, such as the military; with few exceptions, community investigations have failed to indicate differences by age. In only a small number of investigations have data regarding children been itemized separately.^{122,265,371,1108,1225,1286} Table 196.2 presents the relative frequency of symptoms and signs as compiled from eight studies in which both children and adults were included. The hallmark of pneumonia caused by *M. pneumoniae* is fever and cough. The onset of illness usually cannot be demarcated clearly, but malaise, fever, and headache are early complaints. Cough has an onset 3 to 5 days after the beginning of illness and is initially nonproductive. Foy and colleagues³⁶⁸ and Biberfeld and coworkers⁸⁶ noted that 77% and 100%, respectively, of the patients that they studied had maximal temperatures greater than 38.9°C (102°F). Copps and associates²³³ found that 58% of the group that they evaluated had temperatures higher than 39.4°C (103°F) and 4% had temperatures higher than 40.6°C (105°F).

The reporting of headache in association with *M. pneumoniae* pneumonia has varied considerably. Nakao and associates⁸⁴⁹ noted this report in only 8% of subjects, whereas Biberfeld and associates⁸⁶ and Foy and colleagues³⁶⁸ reported it in two-thirds of those studied. Chills and the production of sputum are present in about 50% of ill patients. Again, great differences among investigations are noted, and they probably are related to the relative ages of the patients.

Coryza is unusual in *M. pneumoniae* pneumonia; therefore, its occurrence should suggest another etiologic agent for illness in a specific patient. In a study involving children exclusively, Stevens and colleagues¹¹⁰⁸ noted that coryza occurred more commonly in young children; as might be expected, they found productive cough more frequently in their older patients. Hoarseness, earache, sore throat, gastrointestinal complaints, and chest pain occur in approximately 25% of patients.

On physical examination, approximately 75% of patients have auscultatory evidence of pneumonia and about half have pharyngitis. Remarkable lymphadenopathy, particularly with cervical involvement, is noted in approximately 25% of patients. Twenty-one percent of the patients studied by Foy and associates³⁶⁸ had otitis media. In other studies, this manifestation was noted in about 5% to 10% of cases. Conjunctivitis was observed in almost half the patients reported by Fransen and associates.³⁷⁴ In contrast, except for Jansson and colleagues,⁵⁴¹ who noted conjunctivitis in 3% of their study group, this finding was

not mentioned in the other reports. Similarly, rash was reported in 6%, 11%, and 17%, respectively, in studies in Minnesota, Wisconsin, and Seattle,^{233,369,744} but it was not mentioned in the other studies.

The most common finding on chest auscultation is dry rales, but musical rales with expiration are noted occasionally. Rales usually persist for 2 weeks, and hearing them a month or more after the onset of disease is not unusual. Occasionally, patients have no auscultatory evidence of pulmonary disease throughout their illness in spite of the presence of abnormalities on chest radiographs. During illness, cough becomes increasingly prominent; initially, it is nonproductive but later it may produce a frothy white sputum in older children and adolescents. The sputum also may appear purulent and contain blood. Cough persists for 3 to 4 weeks and longer after nonrespiratory symptoms such as fever and headache have subsided.

In a study of 44 children with lower respiratory tract illness caused by *M. pneumoniae*, Stevens and associates¹¹⁰⁸ noted the following frequencies of symptoms and signs: cough (97%), malaise (82%), vomiting (40%), abdominal pain (35%), headache (32%), rash (20%), fever higher than 38°C (>100.4°F; 78%); rales (78%), pharyngitis (32%), rhonchi (30%), bronchial breathing (27%), and otitis media (27%). Foy and coworkers³⁷¹ found that chills and productive cough were more common in adults than children and that temperatures tended to be higher in children.

In a large study involving 108 children with *M. pneumoniae* infection, wheezing occurred with the acute illness in 40%.⁹⁹² When the children in this study were evaluated 3 years after their acute illness, they were found to have three indicators of lung function that had mean values significantly lower than those in control children.

Few reports specifically describe pneumonia caused by *M. pneumoniae* in young children.^{52,185,222,265,363,437,846,1067,1108,1286} However, a review of the case descriptions available indicates that illness, when it occurs, can be severe and relatively prolonged in contrast to common viral and bacterial infections. Singer and DeVoe¹⁰⁶⁷ reported a 3-year-old severely ill child who had a temperature of 39.4°C (102.9°F), a pulse of 150 beats/min, and a respiratory rate of 40 breaths/min. Diffuse pulmonary involvement

of the right upper lobe and lingular segments of the left lower lobe was observed by radiography, although rales and altered breath sounds could not be heard. The patient's condition worsened over a 6-day period. At that point, specific therapy with erythromycin was instituted, and slow recovery followed. The child had a normal white blood cell count, transiently elevated serum aspartate aminotransferase and alanine aminotransferase values, and microscopic hematuria. Grix and Giammona⁴³⁷ observed two 5-year-old children with extensive pneumonia, pleural effusions, and febrile periods of 10 and 16 days. Stevens and associates¹¹⁰⁸ reported a 5-year-old boy with pulmonary consolidation and aseptic meningitis, and Clyde and Denny²²² described an asymptomatic 3-year-old boy with a "feathery infiltrate" in the right upper lung field. In a family study, Foy and colleagues³⁶³ investigated four children younger than 6 years. In a 4-year-old child, the pneumonia persisted for more than 1 month, and in this child's brother, the illness lasted approximately 2 weeks. We have seen a 4.5-year-old girl with scattered infiltrates throughout both lung fields and febrile illness of 14 days' duration.¹⁸⁶

Severe and extensive pulmonary disease occurs occasionally in *M. pneumoniae* infection.* Massive lobar pneumonia is noted on occasion, and pleural effusions are fairly common findings.† A number of cases of necrotizing pneumonitis with massive pleural effusions have been described.^{62,201,1232} All of these children had protracted periods of fever and respiratory distress. Acute respiratory distress syndrome has been observed, and illness has suggested pulmonary embolism with infarction.^{62,178,350,958,1063,1181} *M. pneumoniae* is a recognized cause of postinfectious bronchiolitis obliterans in children.^{688,689,1227} Chronic intestinal pulmonary fibrosis and fulminant fatal diffuse interstitial fibrosis has been noted in two adults with *M. pneumoniae* pneumonia, and localized bronchiectasis developed in a 20-year-old man at the site of previous acute lung infection.^{199,421,564,1122} Children who had a delay in onset or inadequate duration of macrolide treatment were found by Marc and associates⁷⁴⁷ to have reduced lung diffusion capacity after contracting *M. pneumoniae* pneumonia. Barreira and associates⁶² describe a previously healthy 8-year-old boy who developed necrotizing pneumonitis, septic shock, and meningoencephalitis from *M. pneumoniae*. A 5-year-old girl had severe necrotizing pneumonitis and a 4-year-old boy developed a necrotizing pulmonary cavity.^{889,928} An adult had bronchiolitis obliterans—organizing pneumonia.⁷⁰⁸ *M. pneumoniae* pneumonia is generally more severe in patients with preexisting cardiorespiratory problems, immunodeficiencies, and sickle-cell disease.^{76,211,373,393,546,794,933,1057,1084}

Six patients—three children, one adolescent, and two adults—were found to have lung abscesses in association with *M. pneumoniae* infection.^{199,680,686,903,1061} The illness in the adolescents and adults was characterized by productive cough and chest pain for 2 to 4 weeks. In one patient, clinical recovery and clearance of the pulmonary lesion were dramatic with tetracycline therapy; two other patients received suboptimal therapy but eventually recovered. One of the child cases was a 6-year-old girl who had a 7-day history of cough and a 4-day history of fever.¹⁹⁵ In addition to the abscess, she had pleural effusion, thrombocytopenia, and disseminated intravascular coagulation. Another child was a 10-year-old boy with fever and cough for 15 days refractory to treatment with amoxicillin and ceftriaxone, but with rapid improvement on clarithromycin.⁶⁸⁰ The third child was a 10-year-old boy with West syndrome who developed high fevers, cough, and cytokine storms that did not resolve on antibiotics or steroids, requiring cyclosporine A. Fluid from the abscess was positive by PCR for *M. pneumoniae*, as was serology.⁹⁰³ A 6-year-old boy with 15 days of chest pain, 2 days of fever, and positive serology to *M. pneumoniae* was also found to have a lung abscess, but given that his symptoms improved after several days of empiric vancomycin, ceftazidime, and clindamycin, it was presumed that his disease was caused by secondary infection with another organism.⁹⁸⁷ One 18-year-old man with extensive consolidation of the right

*References 62, 187, 190, 199, 201, 211, 232, 347, 350, 360, 437, 442, 517, 579, 686, 708, 737, 794, 830, 848, 881, 889, 920, 958, 971, 1057, 1061, 1063, 1067, 1084, 1096, 1190, 1232.

†References 51, 164, 190, 196, 201, 223, 264, 347, 350, 437, 714, 719, 831, 845, 848, 881, 926, 1067, 1096, 1190, 1232.

lower lung field had residual pleural scarring 8 months after the acute illness.⁸³¹

Newborns who contracted congenital pneumonia, probably via vertical transmission of *M. pneumoniae*, have been described.^{1092,1179}

Clyde²²¹ reported factors that correlated with *M. pneumoniae* pneumonia in a study of 1139 subjects with community-acquired pneumonia. Positive factors were sore throat, headache, fever of 38.9°C (102°F) or higher, exanthem, family size of four or more, and ear infection. In the same study, pneumonia did not correlate with coryza, leukocytosis ($15 \times 10^9/L$ or more and $10 \times 10^9/L$ or more), preexisting disease, recurrent pneumonia, hospitalization for treatment, or cigarette smoking.

Although recovery from *M. pneumoniae* pneumonia is usually complete, two studies suggest that persistent abnormalities in lung function can occur after illness.^{819,992}

Radiography. Because the classic clinical entity primary atypical pneumonia has numerous causes but often is used as a synonym for *M. pneumoniae* pneumonia, much confusion has ensued about the spectrum of the radiographic appearance of the specific mycoplasmal infection. The radiographic pattern of primary atypical pneumonia is varied, but bilateral, diffuse, reticular infiltrates are common components.^{718,1024,1071} Subsequent study has indicated that the diffuse interstitial pattern is an uncommon finding in *M. pneumoniae* infection and more often is the result of infection with other agents, such as viruses, fungi, and *Chlamydia*.^{121,398,861,951,1172}

Brolin and Wernstedt¹²¹ carefully evaluated the radiographic findings in 56 patients with significant *M. pneumoniae* pneumonia; 21 of the patients were younger than 20 years. They noted the following distribution of different patterns: typical lobar pneumonia (8 patients); predominantly alveolar but not total consolidation (13); interstitial (either reticular or noduloreticular, 20); a combination of lobar pneumonia and other alveolar involvement without total consolidation (2); a combination of lobar involvement and interstitial (10); and a combination of alveolar involvement without total consolidation and interstitial (3). Alveolar patterns were more common in females; interstitial involvement was found more frequently in males. Twenty-two percent of patients had enlargement of the hilar or paratracheal lymph nodes and 14% had pleural effusion.

The persistence of radiographic changes is variable. Brolin and Wernstedt¹²¹ noted that 13% of their patients who underwent follow-up studies had abnormal findings more than 4 weeks after the initial study. They observed that persistence tended to be longer in patients with alveolar disease than in those with interstitial patterns. The degree of clinical symptoms and pulmonary physical findings frequently correlates poorly with the apparent degree of involvement noted on radiographs. In many patients with significant symptoms, only minimal interstitial changes are observed. In other instances, patients with lobar pneumonia often have few clinical findings indicating pulmonary disease.

Lee and colleagues⁶⁶⁶ reported the chest computed tomography (CT) features in 11 children and 5 adults with *M. pneumoniae* pneumonia. The children had the following findings: lobar or segmental consolidation (100%); pleural effusion (82%); lymphadenopathy (82%); and volume decrease of the involved lobe (73%). None of the children had diffuse nodules of ground-glass attenuation, septal thickening, or bronchial wall thickening. In contrast to the children, the adults had diffuse nodules of ground-glass attenuation (80%); septal thickening (40%); lymphadenopathy (40%); bronchial wall thickening (40%); and volume decrease of the involved lobe (20%). None of the adults had lobar or segmental consolidation and pleural effusion. In a retrospective analysis of 64 adult cases of *M. pneumoniae* pneumonia in Japan, the most common CT findings were bronchial wall thickening (81%), followed by centrilobular nodules (78%), ground-glass attenuation (78%), and consolidation (61%).⁸¹⁰

Kim and associates⁶⁰⁰ performed high-resolution CT on 38 children who had been hospitalized with *M. pneumoniae* pneumonia 1 to 2.2 years previously. Abnormalities in two or more lobes, which corresponded to the initial chest radiographic infiltrates, were found in 37% of the children. Young age (<8 years) at the time of hospitalization and high *M. pneumoniae* antibody titer were found to be risk factors for the subsequent abnormalities.

Nonspecific laboratory data. The total leukocyte count in patients with pneumonia caused by *M. pneumoniae* is most often normal, but variation is considerable.^{84,233,321,368,371,375,540,816,1108,1172} In a group of more than 250 children younger than 15 years, Foy and associates³⁷¹ noted that 30% and 6% had total leukocyte counts greater than 10,000 and 15,000 cells/mm³, respectively. In a group of 45 children, Stevens and colleagues¹¹⁰⁸ observed leukocytosis in 33% of patients and leukopenia in one patient. Sixty-seven percent of the children had neutrophilia, and one patient had neutropenia. An increased percentage of band form neutrophils in *M. pneumoniae* pneumonia is an unusual finding.

The erythrocyte sedimentation rate is elevated in all cases,^{84,233,540} and this elevation is usually marked. Biberfeld and colleagues⁸⁴ noted that 16 of 37 patients had erythrocyte sedimentation rates of 50 mm/h. Serologic tests for syphilis are found to be falsely positive on occasion, and serum cold agglutinins and antibodies to *Streptococcus* MG antigen are common findings.^{82,169,173,269} Results of the direct Coombs test are frequently positive, and elevated levels of serum IgM are noted.^{82,330} Urinalysis results are generally normal.

Respiratory Disease Other Than Pneumonia

Common cold and unspecified upper respiratory illness. By strict definition (i.e., significant nasal symptoms, no pharyngitis, and minimal fever), *M. pneumoniae* rarely causes the common cold. However, mild upper respiratory tract illness is noted frequently as the only manifestation of *M. pneumoniae* infection in children, adolescents, and young adults.* The frequency of unspecified upper respiratory tract illness as a manifestation of *M. pneumoniae* infection, in contrast to other manifestations resulting from infection with this agent, varies considerably among studies. Feizi³³¹ studied patients from a country practice in England and noted that 50% of the patients had upper respiratory tract symptoms. Illness in these persons often was prolonged, however, and lasted as long as 7 to 10 weeks. In a review in Scotland, only 3% of 596 *M. pneumoniae* infections were classified as upper respiratory tract illness. In studies of common respiratory tract illnesses in children in which viruses and other agents were sought, *M. pneumoniae* was noted in 2% to 5% of patients with upper respiratory tract illness.^{170,269,715}

Pharyngitis and nasopharyngitis. As noted in Table 196.2, pharyngitis is observed in approximately half of all patients with *M. pneumoniae* pneumonia. However, pharyngitis as the major manifestation of *M. pneumoniae* infection occurs less commonly. Parrott⁹²² found that 12% of children admitted to the hospital with severe "bronchitis-pharyngitis" had *M. pneumoniae* infection. Jensen and associates⁵⁴⁹ noted the frequent occurrence of pharyngitis and otitis media in children infected with *M. pneumoniae*. In a study of 715 children and adolescents with pharyngitis, Glezen and colleagues⁴¹¹ reported that 36.8% had group A streptococcal infection and 3.1% were infected with *M. pneumoniae*. When the *M. pneumoniae* infections were grouped by age, the peak (11.4%) occurred in the 12- to 14-year-old group and none were observed in children younger than 6 years. Five patients with *M. pneumoniae* infection had concomitant group A streptococcal infection, but the illnesses in these cases could not be distinguished clinically from those caused by either agent alone. Cervical lymphadenopathy occurred in approximately 50% of those infected, and the pharyngeal lesion was exudative in 43%. In a study of 127 children with acute pharyngitis, 25 (20%) were found to have serologic evidence of *M. pneumoniae* infection.³¹⁸ Seven (28%) of these children had pharyngeal exudates and 10 (40%) had cervical lymphadenopathy. In a study involving 131 adult patients with pharyngitis, 10.6% were found to have serologic evidence of *M. pneumoniae* infection.⁶¹⁹

Otitis media and bullous hemorrhagic myringitis. Although the incidence has varied across studies, otitis media is noted in approximately 5% of children and adolescents with *M. pneumoniae* pneumonia. The role of *M. pneumoniae* as an etiologic agent in common acute otitis media in children is unclear. Halsted and associates⁴⁵¹ noted that 12% of children with otitis media had serologic evidence of *M. pneumoniae* infection, but they were unable to recover the agent from middle ear fluid. In a study in which children were selected because of *M. pneumoniae* infection

*References 170, 235, 269, 287, 329, 331, 333, 340, 363, 368, 491, 660, 715, 816, 849, 869, 997

in a family member, 47 of 49 children with otitis media had *M. pneumoniae* infection.⁵⁴⁹ Rätty and Kleemola⁹⁶² used PCR to detect *M. pneumoniae* in 16 of 380 (4%) middle ear fluid samples from 138 children with acute otitis media.

In a volunteer study, myringitis developed in 13 of 52 subjects.⁹⁷⁰ Findings were usually bilateral and associated with throbbing pain. The appearance of the tympanic membrane varied from mild injection to severe inflammation with edema. Hemorrhagic areas on the drum were noted in five subjects, and serous-appearing blebs containing blood were observed in two. Bullous myringitis also has been noted only occasionally with natural *M. pneumoniae* infection.^{122,222,363,368,744,1080} In one study of 148 children and adults with *M. pneumoniae* pneumonia, 27 (18%) were found to have bullous myringitis.⁷⁴⁴ Using PCR, Kotikoski and associates⁶²⁶ studied middle ear fluid from 30 children and blister fluid from 12 children with acute meningitis and found no evidence of *M. pneumoniae* DNA.

Sinusitis. Although clinically recognized sinusitis has been reported rarely in patients with *M. pneumoniae* infection, Griffin and Klein⁴³⁵ found radiographic evidence of sinusitis in approximately two-thirds of a group of Navy recruits with *M. pneumoniae* pneumonia. In general, the patients with sinusitis had more prolonged illness than did recruits without sinusitis. Savolainen and colleagues¹⁰¹³ noted that 11 of 310 patients with acute maxillary sinusitis had fourfold or greater rises in complement-fixing antibody to *M. pneumoniae*. A 37-year-old man with chronic sinusitis that evolved into a Pott's puffy tumor was found to have a positive *M. pneumoniae* serology and was treated with doxycycline and surgical excision.²¹⁵ In chronic suppurative maxillary sinusitis, cultures for *M. pneumoniae* have been performed but no organisms were isolated.^{80,1088}

Acute bronchitis. Acute bronchitis characterized by fever, cough, and rhonchi with or without associated pharyngitis is a frequent manifestation of *M. pneumoniae* infection.* Of 40 patients with *M. pneumoniae* infection, Feizi³³¹ reported that 6 had bronchitis, 3 had upper respiratory tract illness plus bronchitis, and 1 had sinusitis plus bronchitis. In contrast to these findings, Hornsleth⁴⁹⁵ noted that only one of 25 patients with *M. pneumoniae* infection had acute bronchitis. In the differential diagnosis of acute bronchitis, *M. pneumoniae* infection accounts for 10% to 20% of cases.^{171,175,269,322,938}

Croup. *M. pneumoniae* infection has been associated only occasionally with croup. Parrott⁹²² found no instances of *M. pneumoniae* infection in a large number of children with croup, and Chanock and Parrott¹⁷⁵ did not list this agent as an etiologic consideration in croup. In contrast, extensive studies in both Seattle and Chapel Hill, North Carolina, have revealed that approximately 2% of croup cases are associated with *M. pneumoniae* infection.^{269,361,412,714} Because no descriptions of clinical illness are available, a reasonable assumption is that croup caused by *M. pneumoniae* infection is generally mild and without distinguishing characteristics.

Bronchiolitis and infectious asthma. The presence of *M. pneumoniae* in the lower airways can trigger a proinflammatory cytokine response similar to that seen in asthmatic and allergic patients.^{460,599,787,792,1239,1277} *M. pneumoniae* pneumonia itself can cause bronchiolitis and wheezing^{52,992}; however, it is also commonly found in asthmatics and is a cause of their symptomatic exacerbations.^{79,509,834,910,1044} Approximately 5% of cases of bronchiolitis are caused by infection with *M. pneumoniae*, but the percentage varies across studies.^{170,171,175,269,287,361,412,714,922} In two large studies, no instances of *M. pneumoniae*-associated bronchiolitis were reported.^{491,495} Horn and associates⁴⁹¹ noted that *M. pneumoniae* was isolated from 6.6% of children with wheezy bronchitis, and Berkovich and associates⁷⁹ found *M. pneumoniae* infection in 7 of 33 episodes of wheezing in asthmatic children. Biscardi and coworkers⁹¹ studied children 2 to 15 years of age hospitalized for severe asthma. Of 119 children with previously diagnosed asthma, 24 (20%) had *M. pneumoniae* infections during the exacerbation that caused their hospital admission. In 51 children with first asthma episodes, *M. pneumoniae* infection was demonstrated in 26 (50%). Children with a first attack of asthma associated with *M. pneumoniae* infection were significantly more likely to have asthma recurrences than children whose primary episodes were

not related to *M. pneumoniae* infection. Lehtinen and colleagues⁶⁷⁴ studied 220 children with wheezing associated with viral infection and found that 5% were coinfecting with *M. pneumoniae*. Freymuth and colleagues³⁷⁹ identified *M. pneumoniae* in nasal aspirate samples by PCR in 3 of 132 children (2%) with acute exacerbations of asthma. Using a sensitive assay for the CARDS toxin, Wood and associates¹²⁵⁹ detected *M. pneumoniae* in 54% of their pediatric patients with acute asthma exacerbation, 65% with refractory asthma, and 56% of healthy controls. Compared to asthmatics with a negative CARDS screen, the former two groups were found to have poorer asthma control and quality of life scores. CARDS-positive asthmatics also had lower levels of IgM and IgG to *M. pneumoniae* than healthy controls. By contrast, a study looking at stable asthmatic pediatric patients without recent exacerbations found that they had higher IgM titers to *M. pneumoniae* than healthy controls.¹⁰⁷⁷

Although a significant number of asthma exacerbations can be linked to *M. pneumoniae* infection, there is still conflicting evidence on the benefit of prophylactic or empirical antibiotic therapy in asthmatics.⁶²³ Macrolides are sometimes advocated not only as an antibiotic but also for their antiinflammatory properties.⁴¹⁷ However, Shin and associates found that children with *M. pneumoniae* pneumonia and a history of atopic sensitization or asthma were also more likely to have infections refractory to macrolide treatment, requiring steroids.¹⁰⁵⁵

Other. Exacerbations of chronic obstructive pulmonary disease have been associated with *M. pneumoniae* infection.^{194,649,786,1075,1246} By culture, Cherry and associates¹⁹⁴ did not obtain any *M. pneumoniae* isolates from the bronchial specimens of adults with chronic bronchitis. However, more recently, Kraft and colleagues,⁶²⁹ using PCR, detected *M. pneumoniae* in the bronchoalveolar lavage or bronchial biopsy specimens of nine of 18 adults with chronic asthma. Smith and associates¹⁰⁷⁵ were unable to show that patients with chronic obstructive pulmonary disease had increased susceptibility to infection in contrast to normal subjects. Illness suggestive of pertussis has been described in three children.^{651,1108} Teig and associates¹¹⁴⁵ studied nasal brush specimens and induced sputum from 38 children with stable chronic lung disease and 42 healthy controls for the presence of *M. pneumoniae* DNA by PCR. Specimens from four (10.5%) of the children with chronic lung disease had *M. pneumoniae* DNA, whereas none of the specimens from control patients were positive. In two provocative studies, Esposito and coworkers^{319,320} found that *M. pneumoniae* infections may play a role in recurrent respiratory infections in children. In their studies, they found that children with tonsillopharyngitis or other respiratory infections caused by *M. pneumoniae* who were treated with azithromycin 10 mg/kg per day for 3 days weekly for 3 weeks were significantly less likely to have recurrent respiratory tract infections than children with similar *M. pneumoniae* infections who did not receive azithromycin treatment.

Exanthem and Enanthem

Exanthem as a manifestation of *M. pneumoniae* infection is a common occurrence, but its incidence has varied considerably among different studies.* In large studies involving children in which *M. pneumoniae* infection was evaluated in a specific geographic area, the incidence of exanthem has varied from 3% to 33%.† Foy and associates³⁶⁸ noted rash in 17% of 319 patients with *M. pneumoniae* pneumonia during a 5-year surveillance period. In a study involving only children, Stevens and colleagues¹¹⁰⁸ noted exanthem in 9% of their patients. Copps and coworkers,²³³ in a community outbreak in La Crosse, Wisconsin, found that 11% of their patients with pneumonia also had rash.

The cutaneous manifestations in *M. pneumoniae* infection are protean. Most common is an erythematous maculopapular rash that is most prominent on the trunk and back; the lesions may be discrete (rubelliform) or confluent (morbilliform). Although not the most common cutaneous manifestations of *M. pneumoniae* infection, erythema multiforme and Stevens-Johnson syndrome are the most often reported and the most

From Cherry JD. Anemia and mucocutaneous lesions due to *Mycoplasma pneumoniae* infections. *Clin Infect Dis* 1993;17(suppl 1):47–51.

serious.* Other unusual cutaneous manifestations include erythema nodosum, pityriasis rosea, varicella-like urticaria, subcorneal pustular dermatosis, acute hemorrhagic edema of infancy, papular purpuric gloves-and-socks syndrome, and Cockade purpura.[†] In Table 196.3, the clinical findings in 29 well-documented cases of *M. pneumoniae* infection with exanthem are presented. Of the total group, all but eight were male, 24 of 29 were younger than 20 years, and 12 of 20 were younger than 11 years. The duration of exanthem was longer than 7 days in all but two patients; all patients were febrile, and in 17 cases, the rash occurred during fever.

Enanthems are also common with *M. pneumoniae* and have been given their own name—*Mycoplasma pneumoniae*-associated

mucositis.^{1012,1162} Oral lesions appear most frequently, followed by ocular and urogenital involvement. Because concurrent cutaneous manifestations are often milder or completely absent, some also to refer to this syndrome as an “atypical Stevens-Johnson” or “Fuchs syndrome.”^{777,795,959,1017,1269} Extensive reviews of published cases of *M. pneumoniae*-related mucocutaneous disease have, in fact, caused some groups to protest against using descriptive terms like Stevens-Johnson syndrome and erythema multiforme.^{144,947,1204} Canavan and associates propose instead the name “*Mycoplasma pneumoniae*-induced rash and mucositis.”¹⁴⁴ They point out that in cases in which *M. pneumoniae* infection is strongly implicated, the patients tend to be younger (2–20 years old), mucositis is prominent with sparse cutaneous findings, and the course is milder and mortality rare (3%) in contrast to those other syndromes. They suggest that making this distinction may help in early management decisions. However, this should not eliminate *M. pneumoniae* from the diagnostic differential in cases of severe mucocutaneous disease. McDermott and associates reported a 19-year-old with mucositis and a diffuse maculopapular, bullous rash that extended to over 30% of his skin, also meeting histologic criteria for toxic epidermal necrolysis.⁷⁷³ A community hospital in Colorado retrospectively analyzed their pediatric records for Stevens-Johnson syndrome cases, and while they found that those with *M. pneumoniae* infection were more likely to have radiographic pneumonia and fewer sites of skin involvement, the majority had severe disease and required prolonged hospitalization and surgical intervention.⁹⁰²

In Table 196.4, the specific mucocutaneous findings in 20 of 29 patients are itemized. Of these, 14 patients had generalized ulcerative stomatitis and 7 had tonsillitis or pharyngitis. Severe conjunctivitis was observed in 8 patients, and this manifestation was seen only in those with vesicular or bullous cutaneous lesions. All 8 patients with severe conjunctivitis also had generalized ulcerative stomatitis. Surprisingly, vesicular or bullous exanthems with oral and eye lesions rarely occurred in females.^{51,764,1108} In an analysis of 42 cases of erythema multiforme seen during a 20-year period, Villiger and associates¹¹⁹³ noted a presumptive or definite diagnosis of *M. pneumoniae* infection in 14 children. Nine of the children were boys (64%) and eight of the illnesses had mucous membrane involvement. Campagna and coworkers describe a 12-year-old boy with acute bronchitis, Stevens-Johnson syndrome, and positive *M. pneumoniae* serology and PCR, whose Stevens-Johnson syndrome findings recurred 8 months later.¹⁴³ Mucocutaneous findings also are present in vasculitic disorders such as Kawasaki disease and Behçet syndrome, both of which have also been associated with mycoplasma infection.^{300,663,1198,1306}

The occurrence of rash as the major manifestation of *M. pneumoniae* infection is probably rare. As noted in Table 196.3, 25 of 29 patients had pneumonia. In a study of 112 patients who had suspected infectious exanthems without pneumonia, Cherry and associates¹⁸⁹ could find none with *M. pneumoniae* infection. However, Foy and colleagues³⁶³ noted a 2-year-old child with only rash, and Stutman¹¹¹¹ reported a 15-year-old boy with Stevens-Johnson syndrome but not pneumonia, from whom the organism was recovered from a vesicular lesion. Ruhrmann and Holthusen⁹⁸⁸ observed frequent cases of mild erythema multiforme without pneumonia.

Many patients with *M. pneumoniae* infection and exanthem have a history of drug administration before development of the rash; this observation suggests the possibility that the rash is drug induced rather than a result of the infectious process.¹¹²⁸ As noted in Table 196.3, 17 patients had received antibiotics before the rash appeared, yet the exanthem was present before the administration of antibiotic therapy in 10. In addition, *M. pneumoniae* has been recovered from the blister fluid of two patients with erythema multiforme.⁷²⁷ Although these data incriminate the infection as a cause of exanthem, the large number of cases in association with the administration of antibiotic raises the possibility that the antibiotic intensifies the dermosensitizing potential of the infectious agent in a manner similar to that noted between Epstein-Barr virus (EBV) and ampicillin in infectious mononucleosis.

Cardiac Manifestations

Cardiac involvement during *M. pneumoniae* infection generally is considered to be unusual.* However, studies of Pönkä⁹⁴⁰ and Sands and

Modified from Cherry JD, Hurwitz ES, Welliver RC. *Mycoplasma pneumoniae* infections and exanthems. *J Pediatr* 1975;87:369–373.

associates¹⁰⁰⁷ and survey data of Noah⁸⁷⁹ and Assaad and Borecka⁴² indicate that *M. pneumoniae* myocarditis and pericarditis are important causes of both morbidity and mortality. In a study of fatal viral and mycoplasmal infections, Assaad and Borecka⁴² noted six cardiovascular deaths related to *M. pneumoniae* infection during a 9-year period. Noah⁸⁷⁹ found that 1% of 700 patients with *M. pneumoniae* infection had cardiac manifestations as the main clinical feature. Pönkä⁹⁴⁰ published findings of a 7-year study involving 560 patients with serologic evidence of *M. pneumoniae* infection. In this group, 69 patients with cardiac manifestations were detected; of these 69 patients, 25 had carditis for which no causal agent other than *M. pneumoniae* could be incriminated. Pönkä⁹⁴⁰ also reviewed the world literature and found a total of 33 other cases of carditis.

Of 25 carefully studied patients, 17 had respiratory symptoms before the diagnosis of carditis and 10 had radiologically confirmed pneumonia. All but four patients had fever. Of the 25 patients, two were younger than 10 years and two were in the 10- to 19-year-old age group. Of the 33 cases in the literature, seven were 20 years old or younger. Of this survey group, 25 of 33 had respiratory illness and in 19 it was recorded as pneumonia.

Of the 25 patients in Finland reviewed by Pönkä, six had pericarditis and the remainder had perimyocarditis. Antibiotic therapy in 11 patients did not appear to shorten the duration of illness or diminish the number of cardiac sequelae. At a 16-month follow-up, 11 patients had persistent cardiac damage. Another interesting aspect of this study was the finding of rises in *M. pneumoniae* complement-fixing antibody titer in five adults with myocardial infarcts.

Chergui and associates¹⁸⁴ described a 45-year-old man with bilateral interstitial infiltrates and second-degree heart block. He was treated with erythromycin; his heart block, fever, and respiratory distress cleared on hospital day 5. Hartleif and coworkers⁴⁵⁹ describe a 16-year-old boy with severe acute onset chest pain with ST segment elevations and reduced myocardial contractility, with rising IgM and IgG titers to *M. pneumoniae*. His myocardial function normalized within days of starting doxycycline, although EKG abnormalities persisted for months.

Mycoplasma may also affect the heart through vasculitis, valvular disease, atherosclerosis, and coronary artery disease, although there are conflicting data on the subject.^{58,223,377,615} Chung and colleagues²¹⁰ analyzed

data from Taiwan's nationwide patient database and found that adults with newly diagnosed *M. pneumoniae* were 37% more likely to develop acute coronary syndrome within the following year compared to the general population.

Hematologic Manifestations

Severe hemolytic anemia has been reported on several occasions in patients with *M. pneumoniae* infection.* Most cases of *M. pneumoniae* hemolytic anemia have been associated with marked pulmonary involvement. Stevens-Johnson syndrome is a common associated finding, and myocarditis has been noted on two occasions.^{232,332,331,595,1108} In general, severity of illness correlates with high titers of cold agglutinins. One unusual case of a 2-year-old boy with severe *M. pneumoniae* IgM-mediated hemolytic anemia without pulmonary symptoms was described.⁶²⁷

The hemolysis may be severe and acute, often with a 50% reduction in hemoglobin concentration. In contrast to uncomplicated pulmonary disease, the leukocyte count in patients with hemolytic anemia frequently is elevated markedly with a predominance of neutrophils. Results of the direct Coombs test are usually positive. Clinical experience suggests that administration of steroids in conjunction with proper antibiotic therapy may be beneficial in this illness. Boccardi and associates¹⁰⁴ observed a 7-year-old boy with hemolytic anemia and transitory paroxysmal cold hemoglobinuria.

Feizi³³⁰ has demonstrated that clinically inapparent compensated hemolysis frequently is associated with *M. pneumoniae* pulmonary infection. Fiala and associates³⁴⁶ noted that bone marrow suppression also contributed to the anemia in a patient whom they studied, and pancytopenia has also rarely been described.⁴⁴⁶ Ruhrmann and Holthusen⁹⁸⁸ reported a hemorrhagic variant of erythema multiforme (Cockade purpura) similar to Henoch-Schönlein disease in *M. pneumoniae* infection; they also noted severe thrombocytopenia not associated with hemolytic anemia. A woman in her third trimester of pregnancy with upper respiratory symptoms developed severe thrombocytopenia and was found to have acute *M. pneumoniae* infection.⁸⁷⁶ Gill and Marrie⁴⁰⁴

*References 180, 184, 195, 326, 332, 385, 429, 440, 588, 594, 595, 627, 644, 651, 685, 716, 844, 878, 915, 1121, 1262.

reported a 27-year-old man who had hemophagocytosis with an *M. pneumoniae* infection. Several pediatric cases of hemophagocytic lymphohistiocytosis in association with *M. pneumoniae* infections have been reported.^{520,615,1276} Also noted was a 4-year-old girl with neutropenia, thrombocytopenia, and acute hepatitis.¹⁷⁹ Severe *M. pneumoniae* infection with pneumonia, thrombocytopenia, and disseminated intravascular coagulation has been described.^{199,207} Hypercoagulability resulting from *M. pneumoniae* infection with evidence of autoimmune antibodies has manifested as venous thrombosis, pulmonary embolisms, and priapism in several cases.^{40,48,56,123,427,531,567,1303} Aviner and colleagues⁴⁸ also describe eight cases of *M. pneumoniae* infection with associated thrombocytopenia not related to disseminated intravascular coagulation. Khoury and colleagues⁵⁹⁷ discuss the case of a 79-year-old woman with anemia and methemoglobinemia believed to be caused by *M. pneumoniae* infection.

Abdominal Manifestations

Nonspecific gastrointestinal findings. Approximately 25% of patients with *M. pneumoniae* pneumonia have nausea, vomiting, diarrhea, or some combination thereof (see Table 196.2). Aside from these complaints, gastrointestinal problems in association with *M. pneumoniae* infection are rare events. Stevens and associates¹¹⁰⁸ found that 15% of a group of 44 children with infection had notable abdominal pain. Referred abdominal pain with pneumonia also has been observed.³³¹

Liver involvement. Liver involvement in *M. pneumoniae* infection is a surprisingly rare event. Levine and Lerner⁶⁸⁴ reported that mild increases in transaminases occur and that acute and chronic active hepatitis has been noted with respiratory symptoms and proven *M. pneumoniae* infection, but they provided no further information. Shin and colleagues¹⁰⁵⁶ did a retrospective analysis of 117 South Korean patients with positive *M. pneumoniae* serology and no other risk factor for hepatitis and found that 25 (21%) had greater than twofold the normal level of transaminases, with up to 40% having greater than fivefold alanine transaminase levels. MacLean⁷³² reported a 13-year-old girl who initially had a sore throat and 9 days later had clinical and laboratory evidence of hepatitis. Murray and associates⁸³⁷ presented a case report of an adult with typical *M. pneumoniae* pneumonia in whom liver function and enzyme studies indicated hepatitis. Helms and colleagues⁴⁷² noted that six of 17 patients with *M. pneumoniae* pneumonia had elevated aspartate aminotransferase values. Enzyme changes have been observed in other case evaluations,^{686,744,1067} some with coagulopathy,¹⁶⁷ and hepatic necrosis has occurred.^{735,835}

Simonian and Janner¹⁰⁶⁵ reported a 12-year-old boy who had pleural effusion, hepatitis, and hemolytic anemia. Narita and associates⁸⁶⁰ noted two children with lymphadenopathy and liver dysfunction. These two patients are of interest because both had mycoplasmaemia and neither had pneumonia. Elevated liver enzymes without respiratory symptoms also have been found in young adults with elevated *M. pneumoniae* serologies.^{663,956,980,1056} A prospective study of 80 pediatric patients with positive *M. pneumoniae* serology and hepatitis showed that these patients tended to have favorable outcomes and that further unnecessary evaluation of the hepatitis should be avoided.⁶⁰³

Splenic infarct. Two children (a 13-year-old girl and a 10-year-old boy) with pneumonia resulting from *M. pneumoniae* infection had splenic infarcts and transient antiphospholipid antibodies.¹²⁵⁷ A 24-year-old man with an elevated *M. pneumoniae* IgM titer developed hepatosplenomegaly and splenic infarct.⁹¹⁹ A 19-year-old woman developed splenic infarct during a coinfection with *M. pneumoniae*, cytomegalovirus and EBV.⁶⁹⁰

Pancreatitis. In 1974, Mårdh and Ursing⁷⁵² reported six patients with respiratory tract illnesses, serologic evidence of *M. pneumoniae* infection, and pancreatitis. In four patients, pancreatic symptoms began 1 to 2 weeks after the onset of respiratory tract illness; in the other two patients, the pancreatitis was subclinical. Diabetes developed in two patients, one of whom died. At postmortem examination, pneumonitis and pancreatitis were confirmed. Nakagawa and colleagues⁸⁴⁷ report on an 8-year-old girl who developed necrotizing pancreatitis 10 days into her treatment for *M. pneumoniae* pneumonia. In a study of pancreatitis, Leinikki and Pantzar⁶⁷⁶ noted that sera from 18 of 56 patients had rises in complement-fixing antibody titer to *M. pneumoniae*. Because none

of the patients in this study had respiratory tract illness suggestive of *M. pneumoniae* infection, the investigators suggested that perhaps the antibody responses were not specific for *M. pneumoniae* infection but were caused by a cross-reacting infection or were the result of autoantigens from pancreatic damage. Leinikki and associates⁶⁷⁷ have conducted further studies; their thought is that the antibody response is nonspecific, but their data neither confirm nor refute this assumption. In another study, Freeman and McMahon³⁷⁷ also noted serologic evidence of *M. pneumoniae* infection in 33% of patients with pancreatitis. Oderda and Kraut⁸⁸⁸ reported a 22-month-old girl with pancreatitis and a rise in complement-fixing antibody titer to *M. pneumoniae*. This child had no respiratory symptoms. Yang and associates¹²⁷⁴ report the case of a 6-year-old girl with fever, drowsiness, respiratory and gastrointestinal symptoms, with rising *M. pneumoniae* titers, who was found to have acute necrotizing pancreatitis with a large pseudocyst.

Renal disease. Mycoplasma infection can lead to renal disease, thought to be due to immune complex deposition. Glomerulonephritis was reported in a few patients with pneumonia^{9,941} or preceding upper respiratory infection symptoms.^{35,181,669} Acute IgA nephropathy following *M. pneumoniae* infection has also been described.¹¹¹⁷ Hemolytic uremic syndrome was reported in a 1-year-old boy with *M. pneumoniae* respiratory infection, although the mechanism was unclear.⁴¹³

Arthritis

Mycoplasmas are a common cause of arthritis in animals other than human beings.^{226,539} Likewise, *M. pneumoniae* infection is associated occasionally with joint manifestations.* In a review of 1259 patients with *M. pneumoniae* infection, Pönkä⁹³⁹ noted transient arthritis in 0.9%. Two patients were found to have Reiter syndrome. Hernandez and colleagues⁴⁷⁷ reported seven instances of arthritis in 38 persons with *M. pneumoniae* respiratory disease. In one patient, the illness lasted 18 months and was associated with the development of rheumatoid factor.

Twenty-one instances of illness suggestive of rheumatic fever have been described.^{77,214,556,650,823,844,855,1031,1243} In all 21 patients, large joints were involved; 18 patients had joint swelling or effusion, whereas three had only pain. Most patients had a history of preceding respiratory illness with sore throat, and 10 of 21 had radiographic evidence of pneumonia. The sedimentation rate was elevated in all patients in whom the test was performed. One child had an erythema marginatum-like rash, as well as polyarthritis and fever.⁸²³ Poggio and colleagues⁹³⁷ reported a child with reactive arthritis 3 weeks after the onset of diarrhea and a respiratory tract infection. Leukocytoclastic vasculitis and polyarthritis associated with *M. pneumoniae* infection has been described in a young adult.⁹³⁴

Muscular Disease

Berger and Wadowsky⁷⁸ reported a 15-year-old girl with right lower lobe pneumonia, hepatitis, and rhabdomyolysis associated with *M. pneumoniae* infection. Minami and associates⁸⁰⁴ reported a 4-year-old boy with pneumonia and a rhabdomyolysis associated with a marked titer rise to *M. pneumoniae* using a passive agglutination assay. Oishi and associates⁸⁹³ described a case of multidrug-resistant *M. pneumoniae* causing rhabdomyolysis in a 7-year-old girl. Rhabdomyolysis in a 25-year-old woman⁸⁰⁴ and a 7-year-old boy²³¹ with *M. pneumoniae* respiratory infections have also been reported. Polymyositis has been noted in association with *M. pneumoniae* infection on six occasions.⁹³²

Ocular and Neurologic Disease

Conjunctivitis is a frequent mucocutaneous manifestation of mycoplasma infection; however, the eye may also be affected through cranial neuropathies, optic papillitis, or anterior uveitis.⁷⁰⁶ A 15-year-old patient suffered bilateral optic disk edema and iritis during an acute *M. pneumoniae* infection.⁹⁹⁹ An 8-year-old boy had bilateral optic neuritis resulting in blurred vision that resolved after 2 months of treatment.¹⁹⁷ A 15-year-old boy had headaches, diplopia, and blurred vision, with a CT angiogram demonstrating vasculitis of the middle cerebral arteries in an area with ischemic demyelination on magnetic resonance imaging.¹³⁸

*References 44, 53, 77, 258, 393, 399, 477, 554, 556, 651, 650, 751, 840, 855, 939, 990, 1243.

Miller Fisher syndrome was described in a 38-year-old man and a 75-year-old woman during the course of an *M. pneumoniae* pneumonia, the former experiencing acute diplopia and the latter with ptosis and ophthalmoplegia.^{667,1068}

Several large community and military studies of *M. pneumoniae* pneumonia and other respiratory tract illnesses are notable in that neurologic disease is not described.^{173,233,321,368,540,816,830} However, other studies, particularly those performed more recently, indicate a surprising spectrum of neurologic illness associated with *M. pneumoniae* infection.* The failure to find neurologic disease in the initial large studies mentioned was probably due not to its absence but to the orientation of the investigators; neurologic disease was not studied under the respiratory investigation protocols. In addition, when neurologic manifestations of *M. pneumoniae* infection occur, it is often in the absence of any respiratory symptoms.^{26,138,858} In three large studies of *M. pneumoniae* illness involving 1856 cases, 2.6 to 4.8% had neurologic illness.^{869,879,942} Assaad and Borecka⁴² noted five fatal *M. pneumoniae* infections in which central nervous system findings were the major clinical manifestations.

In 1973, Lerer and Kalavsky⁶⁸³ reported 5 cases of neurologic disease associated with *M. pneumoniae* infection and analyzed 45 cases from the literature. They noted the following frequencies of specific clinical involvement: generalized encephalitis (30%), spinal nerve roots (30%), meningitis (20%), cranial nerves (20%), focal encephalitis (16%), cerebellum (14%), psychosis (8%), and spinal cord (2%). Combined involvement was noted in 36% of cases; in 79%, a history of antecedent respiratory illness was elicited. Of the patients, 53% were 20 years old or younger, and 15% were younger than 10 years. Eighty percent of the children and adolescents were males. The onset of neurologic disease occurred 3 to 23 days after the onset of respiratory illness, with a mean value of 10 days. Five deaths were noted and 22% of the survivors had residual neurologic deficits.

In a review of 61 patients with *M. pneumoniae*-associated neurologic disease during a 24-year period in Helsinki, Finland, Koskineniemi⁶²⁵ noted that 45 of the patients were children and that all these children had encephalitis. Of the total group, 5 patients (8%) died and 14 (23%) had severe sequelae.

In a study of acute childhood encephalitis in Toronto, Canada, nine of 50 children (18%) with adequate microbiologic study had evidence of *M. pneumoniae* infection.⁶¹⁸ Interestingly, four of the nine children also had evidence of concomitant viral infection. In a further study of encephalitis at the same center during a 5-year period, researchers noted that 50 of 159 children (31%) with encephalitis had evidence of *M. pneumoniae* infection⁹³; in this analysis, 30 of the 50 cases (60%) had microbiologic evidence of other concomitant infections. Respiratory prodromal symptoms preceded the encephalitis in approximately 67% of the patients in whom the diagnosis was based on culture, PCR, or both. Two children had acute demyelinating encephalomyelitis. Long-term neurologic sequelae occurred in 48% to 64% of cases. From 1998 to 2006, 1988 patients with encephalitis of unclear etiology were referred to the California Encephalitis Project.²⁰⁶ *M. pneumoniae* was the most common agent implicated; 111 patients had evidence of *M. pneumoniae* infection and 84 (76%) of these patients were children. In later years, the California Encephalitis Project began to detect an increasing number of cases of anti-N-methyl-D-aspartate receptor encephalitis among children,³⁸¹ an autoimmune process that in some cases has been linked to *M. pneumoniae* infection.^{24,380,1186,1188}

In other studies, aseptic meningitis is reported more frequently; other less common findings include poliomyelitis-like syndrome, bilateral sensorineural deafness, Reye syndrome, cerebral infarction, opsoclonus-myoclonus syndrome, brainstem syndrome, transverse myelitis, psychosis, cerebellar syndrome, radiculopathy, brachial plexus neuropathy, demyelinating polyneuropathy with syndrome of inappropriate secretion of antidiuretic hormone (SIADH), acute disseminated encephalomyelitis, bilateral striatal necrosis, Kluver-Bucy syndrome, Tourette syndrome, obsessive-compulsive disorder, hydrocephalus and

intracranial hypertension, Bell palsy, and Guillain-Barré syndrome. Specific examples include SIADH in a 6-year-old boy,⁷⁰⁴ acute self-limiting parkinsonism in a 9-year-old boy and 12-year-old boy,¹¹³⁴ a 4-year-old boy with acute disseminated encephalomyelitis,²⁵⁹ Bickerstaff brainstem encephalitis in a 9-year-old boy,⁷⁹⁷ hypertensive encephalopathy and Guillain-Barré syndrome in a 7-year-old girl,²³ and new-onset seizures in three pediatric cases that resolved with immunotherapy.³⁷ Arthur and Margolis³⁹ noted the appearance of mycoplasma-like structures in granulomatous angiitis of the central nervous system at postmortem examination of a 35-year-old man.

Mixed Infections

In many studies of *M. pneumoniae* infection, cultural or serologic evidence of concomitant or sequential infection with other infectious agents has been noted.* In a large study of patients hospitalized with acute respiratory illness, Fransen and associates³⁷⁴ found that 64% of patients with rises in complement-fixing antibody titer to *M. pneumoniae* also had antibody titer rises to viral, chlamydial, or bacterial agents. In this group, the most common concomitant infections were with parainfluenza viruses. The occurrence of mixed infection did not appear to have a pronounced effect on clinical manifestations; the only significant difference between patients with mixed infection and those with single *M. pneumoniae* infection was the more common finding of a high erythrocyte sedimentation rate in the former group. In several other large studies of disease caused by *M. pneumoniae*, concomitant infections were common, but no evidence of synergistic or antagonistic roles of one agent for another was noted.^{333,411,816,1097,1098} By contrast, Johansson and associates⁵⁵² did observe more severe disease in patients with mixed viral and bacterial infections, including *M. pneumoniae*, than those with bacteria alone. A different study of 59 children with *M. pneumoniae* pneumonia found 19 cases of coinfection with viruses and nine cases of coinfection with *S. pneumoniae*. While those with *S. pneumoniae* mixed infection were more likely to be younger and have higher durations of fever and hospitalization, those with combined viral and *M. pneumoniae* infection showed no significant clinical differences from those infected by only mycoplasma.²⁰⁰ Hon and colleagues described a 4-year-old girl who succumbed to a severe pneumonia, septic shock, and hemolytic uremic syndrome while infected with *S. pneumoniae*, *M. pneumoniae*, and human metapneumovirus.⁴⁸⁶

Renner and associates⁹⁶⁸ found a lower than expected frequency of seropositivity to *M. pneumoniae* in 91 serum pairs with seroconversion to influenza A virus.

The high rate of possible mixed infections in the large encephalitis study in Toronto is of particular interest.⁹³ In addition to common respiratory viruses and enteroviruses, they noted herpes group viruses, *Bartonella henselae*, and *Mycobacterium tuberculosis*. Similar to *M. pneumoniae*, *M. tuberculosis* is also able to induce cold-agglutinins and hemolytic anemia, and other cases of dual infection with both organisms have been described.¹²⁶³ In studies of *Bordetella pertussis* infection, evidence of mixed infection with *M. pneumoniae* or perhaps serologic cross-reactivity has been found repeatedly.^{182,527,582,1194,1305} Vervloet and colleagues¹¹⁹⁰ found that of 44 cases of *M. pneumoniae* pneumonia, 9 had concomitant *S. pneumoniae* infection.

The observation by Grady and Gilfillan⁴²³ that 81% of patients with Legionnaires' disease also had serologic evidence of *M. pneumoniae* infection is interesting. In the same study, 29% of all patients seropositive for *M. pneumoniae* were also seropositive for the Legionnaires' disease antigen. Comparable studies performed by the Centers for Disease Control and Prevention failed to find a similar rate of high co-positivity in sera obtained in other Legionnaires' disease epidemics. Another study found no serologic relationship between *M. pneumoniae* and *Legionella pneumophila*.⁹⁶⁷ Severe bacterial disease after *M. pneumoniae* infection has been reported occasionally. Stadel and colleagues¹⁰⁹³ noted *Hemophilus influenzae* pneumonia and bacteremia after a mild *M. pneumoniae* illness. Biberfeld and colleagues⁸⁶ reported staphylococcal septicemia in two cases of *M. pneumoniae* pneumonia, and Rykner and associates⁹⁹⁰

*References 2, 22, 32, 34, 47, 49, 59, 66, 74, 94, 198, 224, 280, 288, 313, 415, 454, 465, 481, 526, 573, 598, 606, 612, 621, 637, 654, 681, 700, 758, 798, 828, 834, 877, 883, 887, 917, 921, 945, 984, 996, 1020, 1025, 1029, 1049, 1066, 1098, 1108, 1132, 1149, 1161, 1164, 1174, 1201, 1235, 1245, 1256, 1279, 1280, 1289.

*References 13, 51, 93, 308, 333, 334, 375, 486, 581, 611, 411, 423, 433, 448, 527, 528, 618, 682, 697, 745, 756, 816, 857, 968, 1093, 1097, 1098, 1190, 1191, 1194, 1242, 1223, 1305

recovered pneumococci from the pleural exudate of a patient with *M. pneumoniae* pneumonia. Klein and coworkers reported a 16-year-old girl with *M. pneumoniae* pharyngitis followed by Lemierre syndrome with *Fusobacterium nucleatum* and later complicated by acute EBV infectious mononucleosis.⁶¹¹

Kleemola and Kayhty⁶⁰⁸ found fourfold or greater increases in *M. pneumoniae* complement-fixing antibody titer in 40.7% of 54 patients with bacterial meningitis. However, they thought that this antibody response was not caused by specific *M. pneumoniae* infection but by cross-reactive glycolipids resulting from the bacterial infection.^{608,609}

Lind and associates⁷⁰⁰ reported that four of 19 patients with neurologic disease and *M. pneumoniae* infection had serologic evidence of concomitant viral infection. Wang and colleagues¹²²³ discovered that three of 22 children with *M. pneumoniae*-positive PCR assay also had a positive PCR for respiratory viruses.

Other Disease Associations

Foy and colleagues³⁶³ noted that both ear involvement and pneumonia as manifestations of *M. pneumoniae* infection occurred more commonly in children with previous tonsillectomy. Putman and associates⁹⁵⁰ found that in all but three of 31 patients with sarcoidosis, the serum complement-fixing antibody titer to *M. pneumoniae* was 1:32 or higher, whereas in a similar-sized control group without sarcoidosis, only two persons had titers of 1:32 and none had higher titers. Other interesting observations include multiple birth defects in a newborn exposed to *M. pneumoniae* in utero,¹¹⁵ a tubo-ovarian abscess in a young woman from whom *M. pneumoniae* was isolated in pure culture,¹¹⁵³ Lipschütz ulcers from three females with positive *M. pneumoniae* serology,¹¹⁹² and fever of unknown origin in a 32-year-old man.⁶³⁸

Recurrent Disease

The results of several investigations suggest that recurrent *M. pneumoniae* infection is a frequent finding.^{126,342,1104} Repeat infections can be associated with severe disease, such as pneumonia. In the Seattle studies, second attacks of pneumonia have been documented and similar findings have been observed in England.^{359,370,372,491} Recurrent *M. pneumoniae* infections also occurred throughout the lifetime of a child who was immunocompromised from both poorly controlled human immunodeficiency virus (HIV) and B-cell lymphoma therapy and who died at 8 years of age.¹²⁴⁰

Disease in the Neonate

M. pneumoniae is a common cause of respiratory infection beyond the neonatal period; however, rare cases of intrauterine infection leading to pneumonia in infancy have been found.^{1092,1179}

Diagnosis

Differential Diagnosis

Because the clinical manifestations of *M. pneumoniae* infection are protean and because infections occur commonly in children and adolescents, this agent should be considered in the differential diagnosis of most infectious illnesses. Most important is its consideration in patients with pulmonary disease, in whom illnesses caused by viruses (particularly adenoviruses, parainfluenza viruses, and influenza viruses); *Chlamydomphila psittaci*, *Chlamydomphila pneumoniae*, *Coxiella burnetii*, bacteria (particularly *Streptococcus pneumoniae*, *B. pertussis*, *H. influenzae*, and *M. tuberculosis*); and fungi (particularly *Histoplasma capsulatum* and *Coccidioides immitis*) are the main differential possibilities. Because the clinical manifestations, including the radiographic appearance of the lungs, are frequently similar in the various differential possibilities, the following other factors are important: the status of the host (i.e., normal or immunologically compromised), the environment (i.e., human, animal, or inanimate source), the age of the patient, the incubation period, and the season.

In otherwise healthy children, *M. pneumoniae* is a common cause of pneumonia in those older than 3 years and is the leading cause of pneumonia in older children and adolescents. The lack of coryza is sometimes useful in differentiating *M. pneumoniae* pneumonia from that caused by common viral agents, and elevation of the white blood cell count along with an increase in band form neutrophils is evidence against a mycoplasmal etiologic agent, except in patients with concomitant

hemolytic anemia. The occurrence of exanthem and, in particular, Stevens-Johnson syndrome, should lead the physician to suspect *M. pneumoniae*; similarly, the occurrence of hemolytic anemia, joint manifestations, or neurologic signs and symptoms with pneumonia should lead the physician to strongly suspect *M. pneumoniae* as the etiologic agent. Because the pulmonary manifestations of *M. pneumoniae* infection are not always clinically apparent, a physician investigating an unusual acute or subacute case (i.e., aseptic meningitis or other neurologic illness; exanthem; enanthem; hepatitis; pancreatitis; pericarditis, myocarditis, or both; and arthritis) would be wise to consider the possibility of *M. pneumoniae* as the etiologic agent and to obtain appropriate chest radiographs, as well as definitive cultures and serologic studies.

Specific Diagnosis

Serum cold agglutinins. Despite the considerable confusion in the literature and by physicians in general regarding the diagnostic value of the serum cold agglutination test for *M. pneumoniae* infection, our opinion is that when it is used appropriately, the test is a simple and useful procedure. One cause for confusion was a report in 1966 in which only one of 28 children with positive cold agglutination titers actually had serologic evidence of *M. pneumoniae* infection by complement fixation.¹¹¹⁶ However, this report can be criticized because the study population consisted of 444 children younger than 4 years of age and only 170 of this group had pneumonia. Because cold agglutinins are noted occasionally in the sera of patients of all ages with a variety of illnesses, for useful results, their study should have been restricted to patients likely to have *M. pneumoniae* lower respiratory tract disease.^{190,348,399,696} In various studies of pneumonia, serum cold agglutinins at a titer of 1:32 or higher were found in 50% to 90% of patients with *M. pneumoniae* infection.^{89,169,173,375,399,540,830,1108,1185} In general, the cold agglutinin response correlates directly with the severity of pulmonary involvement; patients with extensive lobar involvement nearly always have positive titers⁸ (1:32), whereas those with only minimal findings on radiographic study frequently have equivocal or negative titers. Positive cold agglutination titers have been observed in 18% of adenoviral pneumonias in a study involving a military population.³⁹⁹ In general, the higher the cold agglutinin titer, the more likely that a particular illness is caused by *M. pneumoniae*.

A rapid screening test for cold agglutinins is available and useful.^{393,434} This test is performed by adding 4 drops of blood to a tube containing sodium citrate or another anticoagulant. The tube is placed in ice water (0°C to 4°C [32°F to 39.2°F]) in a freezer for approximately 30 seconds and then examined immediately for coarse agglutination by tilting the tube on its side. When the tube is warmed, the agglutination should resolve, and it can be reproduced again by repeating the ice-water cooling procedure. A modified version of this rapid test was used in 126 children in an emergency department who had asthma exacerbations.¹⁶⁸ The test had a sensitivity of 78.3% and a specificity of 41.3% in contrast to an IgM ELISA.

Specific antibody determinations. Several specific antibody tests (i.e., growth inhibition, immunofluorescence, indirect hemagglutination, precipitation, mycoplasmacidal antibody, complement fixation, ELISA, adherence inhibition assay, radioimmunoassay, and radioimmunoprecipitation) can be used to measure serum antibodies to *M. pneumoniae*. In the past, only the complement-fixation test was available routinely. A fourfold rise in complement-fixation antibody titer indicates acute *M. pneumoniae* infection. Because complement-fixation antibody in *M. pneumoniae* infection is of relatively short duration, the observation of a fourfold fall in titer also can be useful on occasion in assigning etiologic significance in a particular illness. High single titers ($\geq 1:256$) usually indicate recent infection, but rarely can be used to relate the cause of an illness specifically to *M. pneumoniae*. Because *M. pneumoniae* infection is associated with a relatively long incubation period, the development of antibodies is occurring at the time of acute disease. As a consequence, fourfold changes in titer can occur in a short interval (5 days), and collection of paired sera 5 to 7 days apart usually reveals a significant rise in complement-fixation antibody titer.

Most diagnostic laboratories have replaced the complement-fixation test with commercial immunofluorescence or ELISA for demonstration

of antibodies to *M. pneumoniae* antigens.* These tests, in addition to demonstrating rises in antibody values in paired sera, can identify specific IgM and IgA antibodies in single serum samples. In general, when used by experienced laboratory personnel, both immunofluorescence and ELISA have sensitivities and specificities similar to those of the complement-fixation test for determining significant increases in antibody values in paired serum specimens. In addition, demonstration of specific IgM or IgA antibody in a single serum sample suggests a recent infection. Today, the most common method used for diagnosing *M. pneumoniae* infection in clinical practice in the United States is the single serum IgM assay (although PCR assay is becoming more frequent in the hospital setting). It should be pointed out that most available serologic tests have low specificity and can be falsely positive in other acute infections so that overdiagnosis is common^{73,136,166,247,295,647,875,1129}; therefore, new panels of antigens are being developed.²⁹⁴ Furthermore, the specific IgM and IgA responses after infection may last for several months; therefore, demonstration of these antibodies in a single serum sample may be misleading with regard to the diagnosis of specific illness. Hence, in most instances, paired sera (i.e., 5 to 14 days apart) should be examined to confirm a clinical diagnosis. Also useful is the determination of cold agglutinin titers at the time of IgM ELISA. If an ELISA IgM test is positive and a cold agglutinin test is negative, the physician should be skeptical of the former value.

Culture. With proper media, experienced personnel have little difficulty isolating *M. pneumoniae* from throat swabs of infected patients.^{18,1169} However, because *M. pneumoniae* is relatively slow growing, in most instances requiring more than 1 week of incubation, culture is of less use for diagnosis of routine cases than is serologic study. Cultures should be performed in all unusual situations; specifically, joint fluid, CSF, pericardial fluid, and biopsy material should be cultured. The modified SP-4 medium, which is more sensitive than conventional mycoplasma culture media, coupled with the agar plate immunofluorescence identification procedure, may assist the cultural diagnosis of *M. pneumoniae*.^{979,1169} However, low yield and sensitivity have caused some to recommend abandoning this diagnostic method.¹⁰⁴¹

Detection by nucleic acid amplification and mass spectrometry Tests. A large number of studies have indicated the usefulness of PCR for demonstration of specific *M. pneumoniae* DNA in sputum, throat, nasopharyngeal, blood, CSF, urine, and tissue specimens.[†] Multiple primers have been used to identify gene sequences of the P1 cytoadhesin, ATPase operon, 16S rRNA, 16S-23 S rRNA spacer, tuf, parE, dnaK, pdhA, ptsI, repMp1 noncoding element, and the CARD8 toxin.^{1023,1205} In cases of treatment failure or in communities with high rates of macrolide resistance, specific primers can be made to target several well-characterized mutations.^{551,691,886,1175} This is especially important in Asia, where the rate of resistance is high; however, rural areas may not have the resources to perform PCR. There have been multiple studies in China evaluating loop-mediated isothermal amplification as a simpler and less expensive screening test than standard PCR.^{14,420,523,565,1294}

Using culture with serologic criteria as the comparative standard, several studies have shown excellent sensitivity and specificity using PCR. However, given the high carriage rate of *M. pneumoniae*,¹⁰⁸⁹ correlation of positive results with a clinical picture consistent with infection is critical. In addition, both serology and PCR will occasionally give nonoverlapping false-negative results; therefore a combination of these two diagnostic methods would be optimal.^{575,952,1156}

In a hospital setting where patients may be in more urgent need of a diagnosis despite the broad differential of possible organisms, multiplex PCR has come into favor due to its ability to rapidly screen for multiple respiratory pathogens^{44,886,1043} although this also raises its cost. Matrix-assisted laser desorption/ionization time-of-flight spectrometry can similarly screen for multiple panels of pathogens at once, with enough sensitivity and specificity to identify strain subtypes and the carriage of antibiotic resistance markers.¹²⁶⁸

Treatment

Antimicrobial Therapy

M. pneumoniae is sensitive in vitro to erythromycin, tetracyclines, chloramphenicol, clarithromycin, azithromycin, several aminoglycosides, and quinolones.^{71,269,521,522,542,749,871,1070} It is resistant to all penicillins and for practical purposes to the cephalosporins. In spite of this demonstrated in vitro sensitivity of the organism and several studies that have shown clinical therapeutic effectiveness,* a common misconception of many physicians is that antibiotic therapy is of little value in the treatment of illness caused by *M. pneumoniae*. This idea had its origin before the present era, when many patients with viral pneumonia were given a diagnosis of primary atypical pneumonia and treated unsuccessfully with antibiotics.

In 1961, Kingston and associates⁶⁰⁴ demonstrated the therapeutic effectiveness of demethylchlortetracycline for pneumonia caused by *M. pneumoniae*. Since then, several other antibiotics have been studied carefully and also have been found to be effective against *M. pneumoniae* pneumonia.^{169,269,368,399,540,988,1035,1070,1074} The drugs of choice for pneumonia caused by *M. pneumoniae* are either erythromycins or tetracyclines. Because of the adverse effects of tetracyclines on teeth, a macrolide is the drug of choice in children. Fluoroquinolones are also effective, and have found an increased use in cases of macrolide resistance; however, they also carry a small risk for tendonitis. In *M. pneumoniae* pneumonia, the dose of erythromycin for children is 40 to 50 mg/kg every 24 hours administered every 6 hours for a minimum of 10 days. For adolescents and adults, the dosage of erythromycin or tetracycline is 2 g every 24 hours administered every 6 hours. In general, the effectiveness of antibiotic therapy correlates directly with the severity of pneumonia and the elapsed time of illness before the initiation of therapy.

Azithromycin and clarithromycin both are approved for the treatment of community-acquired pneumonia in children.^{102,457} Their advantage is less frequent dosing, shorter duration of therapy, and less gastrointestinal disturbance in older patients. The azithromycin dosing schedule is 10 mg/kg per day (maximal dose, 1 g/d) on day 1, followed by 5 mg/kg per day (maximal dose, 500 mg/d) for 4 days. The clarithromycin dose is 15 mg/kg per day administered every 12 hours for 10 days (maximal dose, 1 g/d). Macrolide-resistant strains of *M. pneumoniae* were first noted from clinical isolates in Japan in 2000, and are associated with mutations in the 23S rRNA gene.^{760,827} These strains have since spread worldwide, with a rate of 8.2% resistance found in the United States between 2007 and 2010^{149,1270} and 10% to 13% between 2006 and 2014.^{270,1163,1297} Predominantly in Asia, where the rate of resistance can be as high as 95%,¹²⁹⁶ studies have shown that macrolide resistance is associated with longer durations of fever, hospital stay, and treatment.^{1233,1261,1281,1299} However, the clinical relevance is still debated as the overall outcome is usually the same.^{148,808,1163} Even in cases in which resistant strains are present, mild or moderate respiratory infections frequently resolve on macrolide therapy.⁹⁴⁶ This is thought to be due to the immunomodulatory properties of this class of drugs, since much of the disease pathology is caused by inflammatory damage.¹⁰⁰⁸ However, therapy for chronic or lower respiratory infections with *M. pneumoniae* should be promptly changed to effective antibiotics if analysis proves that the strain is resistant. Successful treatment of these strains has been shown using minocycline, doxycycline, or levofloxacin.^{580,726,894} Ciprofloxacin has also been used^{722,994} although it may display an elevated minimal inhibitory concentration.

In all other clinical manifestations of *M. pneumoniae* infection except pneumonia (e.g., nonpulmonary respiratory infection, neurologic disease, and Stevens-Johnson syndrome), antibiotic therapy has not been evaluated adequately. In general, otitis media, pharyngitis, croup, and bronchitis appear to be mild, self-limited illnesses that require no therapy. In more serious illness, such as Stevens-Johnson syndrome and neurologic disease, individual case studies have indicated little evidence of therapeutic benefit with either erythromycin or tetracycline therapy. However, our opinion is that, when diagnosed, most *M. pneumoniae* infections should be treated because there is little to lose and in vitro data suggest the possibility of efficacy.

Corticosteroid Therapy

Steroids have been used in the management of severe pulmonary disease, Stevens-Johnson syndrome, encephalitis, and hemolytic anemia. Although definitive data are lacking, several case studies suggest associated clinical benefit, and one randomized clinical trial of severe pneumonia patients showed significantly faster resolution of symptoms in those who were treated with steroids within 24 hours of admission compared to after 72 hours.⁵⁰⁸ Steroids seem to be particularly useful in treating severe hemolytic anemia.

Several groups^{668,1131,1287} reported on the use of prednisolone or methylprednisolone in the treatment of children with *M. pneumoniae* pneumonia in whom the clinical course worsened while receiving appropriate macrolide therapy. Corticosteroid treatment in these children was related to clinical and radiologic improvement. Cimolai²¹² noted dramatic improvement in a 7-year-old girl treated with methylprednisolone, and in 1964 Capps²³² noted dramatic improvement in an adolescent with persistent fever, severe pneumonia, and hemolytic anemia when treated with a corticosteroid and erythromycin. Lu and associates⁷²² successfully treated six cases of macrolide-resistant *M. pneumoniae* infection with ciprofloxacin and corticosteroids.

Intravenous Immunoglobulin

Intravenous immunoglobulin (IVIG) therapy has been used successfully in certain cases of severe refractory *M. pneumoniae* infection, especially when there is suspicion of an autoimmune process.^{46,120,1042,1285} It is also used in cases of mycoplasma-induced Kawasaki disease. A review of 10 pediatric Stevens-Johnson syndrome cases found that IVIG given in combination with steroids produced a better outcome than IVIG alone.¹²

A 6-year-old girl with brainstem and striatal encephalitis complicating *M. pneumoniae* pneumonia experienced neurologic improvement within 48 hours of administration of IVIG.⁹⁹⁶

Plasmapheresis

Plasmapheresis has been used rarely to treat severe manifestations of *M. pneumoniae* disease, including transverse myelitis with psychosis,²³⁷ autoimmune encephalitis,¹¹⁸⁸ glomerulonephritis,⁹ and severe autoimmune hemolytic anemia.⁴⁵⁴

General Management

Children and adolescents with *M. pneumoniae* pneumonia should be discouraged from engaging in excessive physical activity during the acute illness and for a 2-week period during convalescence because clearance, as observed by radiography, is slow and lags behind apparent clinical well-being. Older children and adolescents should be advised of their contagiousness to others; this risk period exists as long as cough persists, even with successful antibiotic therapy.

Prevention

Because of the marked and prolonged morbidity associated with *M. pneumoniae* infection, which has been particularly troublesome in the military, much effort was directed toward the development of vaccines. In 1965, Jensen and associates⁵⁴⁸ reported encouraging initial trials with an inactivated vaccine. In that study, significant rises in *M. pneumoniae* growth-inhibiting antibody titer developed in 25 of 30 volunteers. Later challenge studies with the same vaccine indicated that nine of 10 volunteers with serum antibody were protected, but illness more severe than that in the unvaccinated control group occurred in vaccinees who did not have an antibody response after initial immunization.¹⁰⁷³ This altered reactivity on challenge suggested a sensitization process perhaps similar to that observed with other inactivated antigen vaccines and indicated the need for caution in further trials.^{242,342} Additionally, because of the large incidence of autoantibody formation in *M. pneumoniae* infection, autoimmune sequelae could potentially be a significant adverse effect with these vaccines.⁵⁵³ Other trials of inactivated vaccines in both adults and children have had varying degrees of success.^{553,694,793,815,1244}

A trial with a live attenuated vaccine (i.e., a temperature-sensitive mutant) gave encouraging results.⁴³¹ However, because further study of natural *M. pneumoniae* disease indicated that reinfection occurs commonly and because sensitization may play a role in pathogenesis,

proceeding slowly in conducting further vaccine trials in children seems prudent.³⁴⁰

DNA vaccines encoding a fusion of the *M. pneumoniae* P1 protein with an *Escherichia coli* toxin were recently found to confer protection in mice.^{1301,1302} A recombinant protein vaccine that included conserved regions of the P1 and P30 cytoadhesins was also shown to induce protective mucosal and systemic antibodies in guinea pigs.⁴⁶³

The degree of contagion of *M. pneumoniae* is relatively low, so isolation methods should be effective in preventing spread of disease. Jensen and colleagues⁵⁴⁹ noted that prophylactic administration of oxytetracycline to family contacts prevented disease but not infection. Azithromycin prophylaxis has been used successfully in two hospital outbreaks of *M. pneumoniae* pneumonia.^{513,607} These studies indicate that in certain circumstances (in particular, high-risk subjects such as patients with sickle-cell disease and high-risk populations), prophylactic administration of antibiotics may be justified.

UREAPLASMA

Properties

Ureaplasmas (formerly T-strain mycoplasmas) are distinguished from all other members of the order *Mycoplasmatales* by their production of urease and their ability to hydrolyze urea.^{909,1047,1048,1140} The morphologic characteristics of *Ureaplasma* spp. in young liquid medium culture are similar to those of other mycoplasmas. Round-ovoid elements approximately 330 nm in diameter with a range of 100 to 850 nm are found; rod-shaped and filamentous structures also occur, and the latter have a length of 2 μ m and a width of 50 to 300 nm.^{97,1048,1250} In clinical material, short bacillary forms with monopointed ends are common findings. Organisms are surrounded by a single trilaminar membrane approximately 10 nm thick with pilus-like structures radiating from the surface. Multiplication occurs by a simple budding process and perhaps by binary fission.

On unbuffered standard mycoplasma agar with a pH of 6.0, *Ureaplasma* spp. colonies are small (20–30 μ m) and circular, with irregular borders, and grow downward into the agar.¹⁰⁴⁸ On buffered agar, *Ureaplasma* spp. colonies are bigger and often have the “fried egg” appearance of typical large colony-forming mycoplasmas.⁷³⁷

Isolation of *Ureaplasma* spp. from clinical material is assisted by the demonstration of urease activity.^{345,1046,1143} In liquid medium containing urea and phenol red, growth of *Ureaplasma* spp. results in the production of ammonia, with a resultant increase in pH and a change in color. Subculture from broth to agar medium that contains urea and manganese sulfate yields dark-brown ureaplasma colonies.

Epidemiology

The main reservoirs of human strains of *Ureaplasma* spp. are the genital tracts of adult men and women.^{36,366,767-769,771,1143,1167,1215,1170} *Ureaplasma* spp. are sexually transmitted organisms that colonize the urogenital tract of women at rates of 30% to 80%.^{114,306,770,1143} One study found that pregnancy was associated with a higher rate of *U. urealyticum* carriage in the cervix in contrast to rates in nonpregnant women (26% vs. 15.3%).⁵⁰ High rates of colonization have been associated with younger age, lower socioeconomic status, sexual activity with multiple partners, black ethnicity, and use of oral contraceptives, although not with HIV status.⁴²²

In general, cervicovaginal colonization with *Ureaplasma* spp. and *M. hominis* during pregnancy is not predictive of adverse outcomes, such as premature delivery, low-birth-weight infants, and spontaneous abortion.^{160,202,316,422,1215} However, preterm labor has been associated with the altered microbial environment found in bacterial vaginosis, although there have been conflicting reports on whether genital mycoplasmas may play a role as well.^{279,670} High-density genital ureaplasma colonization has been associated with chorioamnionitis and preterm delivery.^{5,562,905} It is capable of invading the upper genital tract in a subpopulation of women, as evidenced by their isolation from the endometrium,⁶⁵² placenta,^{311,468,638} and amniotic fluid.^{151,156,159,357,428,497,1155,1282,1283} These organisms also have immunogenic surface lipoproteins that may trigger inflammatory reactions that lead to preterm premature rupture of membranes and/or preterm labor.^{456,562,655,885,929}

Ureaplasma spp. have been strongly associated with histologic chorioamnionitis, postpartum fever, and endometritis.^{30,31,152,159,160,468,488,1086}

Infants become colonized during passage through the birth canal of an infected woman.^{371,610,671,1120,1215} With ruptured membranes, the infant can be infected in utero.⁶¹⁰ *Ureaplasma* spp. have been recovered from the following sites in newborn infants: throat, nose, genitourinary tract of girls, urine of boys, external auditory canal, umbilicus, and perineum. Not all infants of infected women become colonized, and neonatal colonization tends to not persist. In one study in which *Ureaplasma* spp. were recovered from 38% of girls and 6% of boys at birth, follow-up during a 2-year period revealed a decreasing prevalence of colonization; at 2 years, none of the children had positive cultures.³⁶⁷ However, in one large study of pediatric patients with chronic respiratory disease, 8.8% carried *U. parvum* and 2.8% carried *U. urealyticum* in their respiratory tract.⁹²⁴

During prepubertal childhood, *Ureaplasma* spp. are recovered only rarely from urine or genital specimens.^{364,671} After puberty, colonization is a common occurrence and is primarily the result of sexual contact.^{765,767,769} Colonization in adults is related directly to sexual activity. In population studies, *Ureaplasma* spp. are rarely isolated from persons with no sexual experience, but they occur in approximately 50% of men and 75% of women for whom sexual intercourse with three or more partners is reported.

Clinical Manifestations

Because ureaplasma can be recovered with considerable frequency from the throat, eyes, and genitourinary tract of babies and from the genitourinary tract of postpubertal males and females who are well, establishing cause-and-effect relationships in disease frequently has been difficult. Studies suggest the following disease associations with ureaplasma in human genitourinary and reproductive disease: good to strong association with nongonococcal urethritis, prostatitis, and urethral syndrome; moderate association with epididymitis, involuntary infertility, repeated spontaneous abortion and stillbirth, chorioamnionitis, and low birth-weight; weak association with urinary calculi, pyelonephritis, Reiter disease, and pelvic inflammatory disease; and no association with Bartholin gland abscess, vaginitis, cervicitis, postabortal fever, and postpartum fever.*

Adverse Pregnancy Outcomes and Infertility

There has been much debate regarding genital mycoplasmas and whether they play a role in spontaneous abortion and premature labor, although supporting evidence is growing.^{315,838,1195,1215} A study at a Cincinnati hospital that included 443 moderate-to-late preterm (32–36 weeks' gestation) births found that 9.9% of those placentas were positive for infection by culture or PCR.¹¹¹⁸ Not only were *Ureaplasma* spp. the most commonly isolated organisms (>68% of all isolates), but their presence was significantly associated with choriomnionitis by histology and the presence of inflammatory markers, such as G-CSF. The Alabama Preterm Birth Study in 2008⁴¹⁴ examined umbilical cord blood cultures for genital mycoplasmas in very preterm newborn neonates (i.e., 23–32 weeks' gestation). They found *U. urealyticum*, *M. hominis*, or both in 23% of the samples and more commonly in infants of nonwhite mothers (27.9% vs. 16.8%, $P = .016$), mothers younger than 20 years of age, those having a spontaneous rather than an indicated preterm delivery (34.7% vs. 3.2%, $P = .0001$), and those delivering at an earlier gestational age. Infants with positive cultures were more likely to have had intrauterine infection and inflammation, as shown by positive placental cultures, elevated cord blood IL-6 levels, and placental histology. Positive growth for these genital mycobacteria in cord blood also was associated with systemic inflammatory response syndrome (41.3% vs. 25.7%, $P = .007$). No significant difference between groups was found for intraventricular hemorrhage or death. Romero and Garite⁹⁷⁹ commented on particularly significant findings from this study, including that genital mycoplasmas caused bacteremia in 1 in 4 of very preterm newborns, most commonly *U. urealyticum*, although a large number (i.e., 22% of those with positive umbilical blood cultures) had simultaneous colonization with *M. hominis*. They raise the question of whether these organisms should be screened

for in routine prenatal and perinatal care, and whether standard neonatal sepsis antibiotic regimens should be adjusted to cover them. Kwak and colleagues⁶⁴⁵ found that preterm infants born to mothers with vaginal cultures positive for both *U. urealyticum* and *M. hominis* were significantly more premature, had lower birth weights, and were more likely to have histologic chorioamnionitis and require NICU admission, compared to those born to mothers infected with ureaplasma alone. By contrast, a retrospective study of 153 births with preterm (24 to 36 weeks' gestation) premature rupture of membranes found *Ureaplasma* spp. and/or *M. hominis* involvement in only 15 cases, none of which showed a significant association between bacterial load and signs of a high fetal inflammatory response.⁵⁶³ Waites and associates¹²¹⁷ wrote a comprehensive review of the literature trying to support a link between genital mycoplasmas and adverse outcomes. Comparisons of recent findings in prophylactic antibiotic use to forestall these outcomes, however, were inconclusive, possibly as a result of the varied methods used.

Genital mycoplasmas can invade the upper genital tract and cause inflammation; this has been proposed as a potential cause of infertility.^{445,516} In addition, some *Mycoplasma* spp. can bind and affect sperm; infertility in men has been associated with these infections.^{272,395,998} These topics will not be discussed further because they are outside the scope of this text's pediatric focus.

Nongonococcal Urethritis

Nongonococcal urethritis (NGU) occurs more commonly than gonococcal urethritis in men in most developed countries.^{458,530,763} Approximately 40% of cases of NGU are caused by *Chlamydia trachomatis*, and 20% to 30% are the result of ureaplasma infection.^{109,110,239,483,768,1015} Clinical differentiation of disease caused by *C. trachomatis* and ureaplasma has not been studied, but NGU and gonococcal urethritis have been evaluated comparatively.^{453,530,671,1200}

The incubation period in NGU is relatively long, with most cases occurring 10 to 20 days after exposure, whereas with gonorrhea the period is shorter, usually less than 1 week.⁴⁵³ The onset of symptoms in NGU is generally more gradual than that associated with gonorrhea. Virtually all men with gonorrhea have a urethral discharge, and most have both discharge and dysuria. In contrast, Jacobs and Kraus⁵³⁰ found that only 38% of men with NGU had both dysuria and discharge. In the same study, 15% of patients with NGU had only dysuria, whereas only 2% of those with gonococcal urethritis had a similar problem. On examination, Handsfield¹⁴⁵³ found the discharge in NGU to be purulent in 36% of his cases, nonpurulent in 9%, and of an intermediate character in the remaining 55%. In contrast, 73% of patients with gonorrhea had a purulent discharge, 27% had an intermediate discharge, and none had a nonpurulent discharge. Because of the more gradual onset and the usually less severe symptoms, patients with NGU are less prompt in seeking medical care than those with gonorrhea. Jacobs and Kraus⁵³⁰ found that 76% of patients with discharge and gonococcal infection came to the clinic within 4 days of onset, whereas only 43% of patients with similar NGU visited the clinic within 4 days of disease onset. Without treatment, nongonococcal urethritis symptoms subside gradually in some patients during a 1- to 3-month period.⁹⁰⁷

After penicillin, ampicillin, or spectinomycin treatment of men with urethral gonorrhea, urethritis recurs (postgonococcal urethritis) in many patients.⁴⁸⁵ Studies of postgonococcal urethritis indicate an etiologic role for *C. trachomatis*; genital mycoplasmas are probably responsible for some cases,⁹⁰⁸ especially as persistent urethritis after doxycycline treatment also has been reported.¹²⁵²

A 7.5-year-old sexually inactive boy with recurrent urethritis associated with *U. urealyticum* infection has been described.¹⁰³⁹

Other Infections

Ureaplasma has also been associated with postoperative mediastinitis in adults.^{390,396,451} It was recovered from the synovial fluid of a 21-year-old woman on immunosuppression for juvenile idiopathic arthritis who developed a genitourinary infection, soft tissue abscesses, and septic arthritis of the knee and hip.³⁹⁷

Disease in the Neonate

Transmission. Vertical transmission of *Ureaplasma* spp. and *M. hominis* from a colonized mother to her newborn occurs in utero or during

*References 130, 156, 161, 311, 639, 648, 774, 1100, 1110, 1143, 1159, 1171.

delivery.^{7,16,424,1001,1215} The relative frequency of occurrence at each time point is not fully known. Acquisition of mycoplasmas by newborns can occur at the time of delivery through contact with a colonized birth canal, but they also have been found on the mucosal surfaces of newborns delivered by cesarean section performed before the onset of labor and rupture of amniotic membranes.^{1003,1120} In utero transmission occurs either transplacentally by the hematogenous route or via an ascending intrauterine infection from a colonized maternal genital tract. Mycoplasmas have been isolated from maternal blood at the time of delivery and from umbilical cord blood, amniotic fluid, endometrium, chorion-amnion, placenta, and aborted fetal tissue. Specific IgM antibody responses have been detected in neonatal serum. Postpartum or nosocomial transmission probably occurs, but definitive proof is lacking. The idea was suggested by the finding of ureaplasma colonization in infants at 3 to 4 weeks of age who were not previously shown to be colonized with *Ureaplasma* spp. while in a neonatal intensive care unit (NICU).¹⁰⁰³

The rate of vertical transmission of *Ureaplasma* spp. ranges from 0.9% to 55% in full-term infants and 8.5% to 58% in preterm infants, depending on the number and type of mucosal surfaces sampled.^{16,208,890,1001–1003,1120} *M. hominis* has been isolated from the nasopharyngeal aspirates and gastric secretions of 30% to 42%^{208,209} and 8%,⁴²⁴ respectively, of infants born to colonized mothers. The rate of vertical transmission of *Ureaplasma* spp. is not affected by the method of delivery or the duration of time after rupture of membranes. Vertical transmission is increased significantly in the presence of chorioamnionitis and intraamniotic infection.^{276,1058} Colonization of newborn infants increases with decreasing gestational age and birthweight¹⁰ and is highest in infants weighing less than 1000 g at birth.¹⁰⁰³ Female newborns are more likely than males to be colonized with ureaplasma because the vagina is a common site of colonization.^{366,1002}

Colonization with ureaplasma persists through early infancy; 68%, 33%, and 37% of full-term newborns colonized in the throat, eye, and vagina, respectively, are still colonized at 3 months of age.^{940,1120} However, most of them lose colonization by the time they reach 2 years of age.^{315,366} Among preterm infants, 65% remain colonized at the time of discharge from the NICU or at 28 days of life.¹⁰⁰³ Overall, the prevalence of ureaplasma colonization varies from 2% to 86% among infants admitted to NICUs, and as many as 14% to 41% of infants have endotracheal aspirate cultures positive for *Ureaplasma* spp.^{257,296,469,525,900,1001}

Clinical Manifestations

The role of *Ureaplasma* spp. in neonatal disease continues to be investigated and defined. *M. hominis* and *Ureaplasma* spp. have been recovered from the lungs, brain, heart, and viscera of aborted fetuses and stillborn infants, with histologic findings of bronchopneumonia present in the lungs.^{734,1123} *Ureaplasma* spp. were isolated from blood in as many as 34% of infants younger than 34 weeks' gestational age.⁸⁹⁹ *Ureaplasma* spp. were isolated from blood in as many as 34% of infants younger than 34 weeks' gestational age. Twenty-six percent of preterm infants had positive endotracheal aspirate cultures for *Ureaplasma* spp. in one study.¹⁵⁸ Genital mycoplasmas also have been isolated from the blood, urine, CSF, and lung tissue of infants with clinical signs of infection. These organisms frequently colonize the mucosal surfaces of newborns,^{610,1002} and ascribing disease often is difficult. However, isolation from normally sterile body fluids in symptomatic infants has led to the recognition that these organisms are neonatal pathogens.

Chorioamnionitis

In a study of 249 puerperal women and their babies, Shurin and colleagues¹⁰⁵⁸ noted on histologic examination of the placentas that *Ureaplasma* spp. were recovered from 37.5% of babies whose placentas showed chorioamnionitis and from only 19% of those with normal placentas. In this study, no adverse effects could be attributed to either the placental lesions or colonization of the babies. Another group found that *U. urealyticum* and *M. hominis* in the umbilical cord was associated with funisitis, but the presence of these organisms in the placenta, tracheal aspirate, or gastric fluid of preterm infants did not show a significant difference in the presence of chorioamnionitis in the mother or chronic lung disease in the baby.³⁰⁴ Caspi and associates¹⁵¹ reported a 32-year-old

woman with amnionitis in whom ureaplasma was recovered from blood. After delivery, the same organism was recovered from the blood of one of the twin infants.

Pneumonia

Fatal neonatal pneumonia in a term infant was documented by isolation of ureaplasma from lung tissue at autopsy, with demonstrated elevated serum IgG and IgM titers to the organism.⁹⁵⁴ Afebrile pneumonitis was reported in infants younger than 3 months of age.¹⁰⁹⁴ Pneumonia and persistent pulmonary hypertension were documented in three infants from whom *Ureaplasma* spp. were isolated from blood, endotracheal aspirates, pleural fluid, or lung tissue (or any combination of these sites) at autopsy.¹²¹¹ Cultrera and colleagues²⁴⁸ reported finding an association between colonization of the lower respiratory tract by *Ureaplasma* spp., particularly by *U. parvum* in preterm newborns, and respiratory distress syndrome. The potential role of ureaplasma in neonatal pneumonia^{131,386,408,913} has been strengthened by demonstration of histologic evidence of pneumonia in the lungs of newborn mice and premature baboons; ureaplasma isolates were obtained from the pleural fluid, lung biopsy specimens, and lung tissue of these experimental pneumonia models.^{157,986,1220} Crouse and associates²⁴³ demonstrated that pneumonia is produced in newborn mice, but significantly less often in mice older than 14 days, and is potentiated by oxygen therapy. *Ureaplasma* spp. have been shown to induce ciliostasis and mucosal lesions in human fetal tracheal organ cultures.¹⁵⁷ In addition, ureaplasma can induce the production of alveolar macrophage proinflammatory cytokines in vitro,⁶⁸⁷ and both *Ureaplasma* spp. and *M. hominis* stimulate the production of tumor necrosis factor- α and inducible nitric oxide synthase from murine macrophages.²⁴⁴ Viscardi and colleagues¹⁹⁷ developed the first juvenile mouse model of ureaplasma pneumonia. Their data suggest that *Ureaplasma* alone may cause limited inflammation and minimal tissue injury in the early phase of infection but may promote a mild chronic inflammatory response in the later phase of infection (days 14–28), similar to the process that occurs in human newborns.

Chronic Lung Disease

Isolation of *Ureaplasma* spp. from endotracheal secretions, the nasopharynx, the throat, or gastric aspirates (or any combination of these sites) has been associated with chronic lung disease of prematurity. Development of chronic lung disease was described in low-birthweight infants whose respiratory tracts were colonized with *Ureaplasma* spp. in the first week of life.*

The results from a meta-analysis performed by Wang and colleagues¹²²⁹ involving 17 publications supported a significant association between ureaplasma colonization and the subsequent development of chronic lung disease. Crouse and associates²⁴⁵ noted that infants who weighed 1250 g or less at birth, had respiratory tract disease, and were colonized with *Ureaplasma* spp. in their tracheal secretions were more likely to have radiographic evidence of more severe pulmonary disease than were infants who were not colonized. Similar findings were made by Honma and coworkers,⁴⁸⁸ who noted that infants younger than 32 weeks' gestational age with elevated white blood cell counts and *U. urealyticum* colonization were more likely to develop infection-related chronic lung disease. These findings were not supported by studies by Cordero and colleagues,²³⁴ who did not detect any specific radiographic abnormalities in 183 infants with a birthweight of 1250 g or less and who had endotracheal colonization with *Ureaplasma* spp., gram-negative cocci, or gram-negative bacilli. However, Ollikainen and associates⁸⁹⁶ found that preterm infants colonized with *Ureaplasma* spp. had higher leukocyte counts on the first 2 days of life and that they required high-frequency oscillatory ventilation more often than those not colonized. In addition, the isolation by Walsh and colleagues¹²²¹ of *Ureaplasma* spp. from the lungs of infants with chronic lung disease implies an invasive bacterial process as part of the pathogenesis of lung injury. In a retrospective study of 60 ventilated babies born at less than 30 weeks' gestation, 25 of whom were ureaplasma culture-positive, Theilen and associates¹¹⁵² found that the ventilated babies with ureaplasma in their tracheal

*References 3, 15, 17, 34, 57, 68, 109, 128, 140, 150, 156, 161, 180, 220, 222, 223, 235, 254, 301, 309, 488, 630, 927.

secretions had a clinical and radiologic course different from that of the infants who were culture negative. Specifically, they had less acute lung disease but an earlier onset of chronic lung disease.

In contrast to these studies, Heggie and colleagues,⁴⁶⁹ Da Silva and associates,²⁵⁷ and Couroucli and colleagues²⁴¹ found no association between ureaplasma and the development of bronchopulmonary dysplasia (BPD). Bowman and colleagues¹¹¹ used erythromycin to treat extremely-low-birthweight infants colonized with ureaplasma and found no association between the initial colonization and the development of chronic lung disease. They also called attention to the fact that in the study by Heggie and coworkers,⁴⁶⁹ a substantial proportion of the colonized infants were treated with erythromycin, which might explain the lack of an association between colonization and subsequent chronic lung disease. In 1997, van Waarde and associates¹¹⁸⁷ noted that preterm infants who were at the highest risk for the development of chronic lung disease (i.e., those with the lowest gestational age and birthweight) also were the ones most likely to be colonized with *Ureaplasma* spp. Castro-Alcaraz and coworkers¹⁶² found that a persistently positive colonization pattern, which accounted for 45% of the ureaplasma-positive infants, was associated with a significantly increased risk for the development of chronic lung disease.

One theory suggests that ureaplasma is not the primary cause of BPD but might be the cause of undetected pneumonia.¹⁵⁵ This pneumonia results in an increased requirement for supplemental oxygen, and BPD is the result of oxygen toxicity caused by the supplemental oxygen therapy. Viscardi and associates,¹¹⁹⁶ using the preterm baboon model, suggested that a prolonged proinflammatory response initiated by intrauterine ureaplasma infection contributed to the early development of fibrosis and altered developmental signaling in the immature lung.

The possibility that ureaplasma colonization of the respiratory tract induces an inflammatory response without direct pulmonary invasion and infection cannot be excluded.^{438,729} It has been supported by the finding of elevated levels of tumor necrosis factor- α , IL-6, IL-8, and monocyte chemoattractant protein-1 in the tracheal secretions of colonized infants,^{34,157,439,743,1101} as well as by elevated white blood cell counts and eosinophilia in infants whose respiratory tract is colonized by *Ureaplasma* spp.^{892,896,916} The contribution of *U. urealyticum* and *U. parvum* was evaluated by Heggie and colleagues.⁴⁶⁹ Both species colonized preterm infants with a birthweight of less than 1500 g; however, no association was seen between endotracheal colonization with either species and the development of chronic lung disease. In a study performed by Katz and colleagues,⁵⁷⁷ *U. parvum* was detected more often than *U. urealyticum*, but the researchers found no significant difference or trend in the prevalence of either species between infants with or without BPD. Similarly, the Alabama Preterm Birth Study showed no association between ureaplasma infection and respiratory distress syndrome (RDS).⁴¹⁴ However, Cultrera and associates²⁴⁸ did find a strong association in preterm infants of RDS development and colonization, especially with *U. parvum*.

In a meta-analysis, Schelonka and colleagues¹⁰¹⁹ reviewed 36 articles in which cohorts of neonates were screened for the presence of ureaplasma by culture with or without PCR and monitored prospectively for the development of BPD. They concluded that colonization with ureaplasma was associated with higher reported rates of BPD. However, the greatest reported effect was seen in the small studies, and, therefore, reporting bias may be partially responsible for the higher rates of BPD in colonized infants. The Alabama study could also find no significant association with BPD when adjusted for maternal race, infant gestational age, and gender.⁴¹⁴

Central Nervous System Infections

Both *Ureaplasma* spp. and *M. hominis* have been isolated from the CSF of both full-term and preterm infants.* The repeated isolation of these organisms from the CSF of predominantly preterm infants with suspected meningitis and their association with a CSF pleocytosis consisting of polymorphonuclear or mononuclear cells, hypoglycorrhachia, and elevated protein content support their role in causing neonatal meningitis.

Waites and colleagues¹²¹⁶ noted hemiplegia, hydrocephalus, and developmental delay in survivors. Glaser and associates⁴¹⁰ report the case of a 26-week-gestation infant born to a mother who underwent cerclage. The baby had progressive hydrocephalus and meningitis for over 200 days before diagnostic tests for mycoplasma were performed, which were positive for *U. parvum* by CSF culture and PCR.

Isolation of *Ureaplasma* spp. from the CSF of preterm infants also has been associated with severe intraventricular hemorrhage.^{4,898,1216} However, Likitnukul and associates⁶⁹² cultured the CSF and blood of 203 infants with suspected sepsis and failed to isolate *Ureaplasma* spp. Primarily in full-term infants, isolation of *Ureaplasma* spp. and *M. hominis* often has been associated with minimal if any CSF abnormalities, and these infants have done well without receiving specific antimicrobial therapy.^{470,862,1019,1180,1213} In such instances, the presence of these organisms remains of unclear clinical significance, and their role in producing disease is questionable.

Other Infections

Nonimmune hydrops fetalis was reported in a newborn at 32 weeks' gestation in whom *U. urealyticum* was isolated from bronchial secretions and lung and brain tissue at autopsy.⁸⁹⁷ Osteomyelitis of the femur was associated with isolation of ureaplasma from the blood of a preterm infant.⁴⁰⁷ Ureaplasma was recovered from a scalp abscess at the site of an internal fetal electrode monitor.⁴⁵²

Differential Diagnosis

In clinical practice, the most important differential consideration is between gonococcal infection and nongonococcal urethritis. Although the symptoms of the two illnesses are frequently different, sufficient overlap exists to render arriving at a specific diagnosis without laboratory aid hazardous. Microscopic examination of a urethral specimen is essential. In most instances, the observation of gram-negative cell-associated diplococci on Gram stain is sufficient for a diagnosis of *Neisseria gonorrhoeae* infection. When smears reveal polymorphonuclear neutrophils without organisms suggestive of gonococci, a specific bacterial culture should be performed. Because infection with multiple agents occurs commonly and postgonococcal urethritis is a frequent problem, thorough investigation of initial illnesses in adolescents with cultures for bacteria, chlamydia, and ureaplasma is advised.

Because of the frequent colonization of newborn infants with mycoplasmas, an etiologic role for these agents cannot be supported by detection of organisms on mucosal surfaces only. However, isolation from normally sterile sites would support further workup and possibly treatment.

MYCOPLASMA HOMINIS

Properties

Three basic morphologic forms of *M. hominis* have been observed by phase-contrast microscopy: coccoidal cells 30 to 80 nm in diameter, diploforms and filamentous forms with a thickness of 30 to 40 nm, and forms with variable lengths reaching 40 μ m or more.^{103,117,119,277} Brett¹¹⁸ studied newly isolated strains and noted that coccoid forms and ring- or disk-shaped cells were predominant; with some strains, filamentous forms of variable length also were noted. Multiplication occurs by binary fission, by fragmentation of filaments and rings, and by budding.^{103,973}

Anderson and Barile²⁹ studied the ultrastructure of *M. hominis* and noted considerable variability in internal components. In some cells, ribosome-like granules in the cytoplasm and a more central area of net-like strands were present, suggestive of a nucleus. Other cells had only irregular densities within the cytoplasm. In some instances, dense cytoplasmic bodies were observed; in other cells, vacuoles were seen.

On mycoplasma agar, *M. hominis* colonies are approximately 200 to 300 μ m in diameter and have the typical mycoplasmal "fried egg" appearance.¹¹⁴³ *M. hominis* grows on ordinary blood agar and produces pinpoint nonhemolytic colonies. It metabolizes arginine to ammonia, so that arginine-supplemented liquid medium with a pH indicator (phenol red) can be used for primary isolation. *M. hominis* can be identified specifically and differentiated from other human mycoplasmas that metabolize arginine by growth inhibition by specific antibody.

*References 25, 135, 392, 403, 462, 479, 605, 750, 775, 862, 1038, 1059, 1095, 1180, 1213, 1216.

Multiple membrane proteins that mediate the adhesion of *M. hominis* to cells of the urogenital tract and to trichomonas have been identified.^{475,489} Attachment is to sulfated glycolipids of the host cells.⁹⁰¹

Epidemiology

M. hominis colonizes the urogenital tracts of sexually active adults,^{371,765,767,769–771,1143,1215} with the rate of carriage in women estimated to be 20% to 50%.^{114,770,1143} One study that found an association between pregnancy and ureaplasma colonization noted only minimal rates of *M. hominis* carriage and no significant difference in rate in pregnancy.⁵⁰ The rest of its epidemiology follows the same characteristics as those listed for the *Ureaplasma* spp. Similarly, the simple presence of *M. hominis* in the lower genital tract during pregnancy is not predictive of adverse outcomes^{147,160,316,1215} and has a controversial role in causing spontaneous abortion and preterm delivery.^{315,841,1215} One study suggests that genetic differences between strains may account for the variable outcomes seen.¹⁹ Like the *Ureaplasma* spp., it can invade the upper genital tract. *M. hominis* has been shown to be a cause of pelvic inflammatory disease, postpartum septicemia, and endometritis,^{157,586,772,866,936} and it has been associated with surgical wound infection after cesarean delivery.^{624,731,972} It can be recovered from the oral cavity of 1% to 5% of normal adults.¹⁰⁸⁵ In one large study, it was found in the respiratory tract of 4.7% of pediatric patients with chronic respiratory tract disease.⁹²⁴

M. hominis has been identified inside *Trichomonas vaginalis*, where it is believed to play a symbiotic role.^{271,824} *T. vaginalis* strains harboring *M. hominis* were found to have increased virulence behavior.¹¹⁸² Conflicting reports exist of metronidazole resistance being conferred by *M. hominis*.^{137,253,1267} An unrelated, novel mycoplasma species isolated almost exclusively from women with *T. vaginalis* infection has also been described.³⁴⁴

Clinical Manifestations

Studies suggest the following disease associations with *M. hominis* in human genitourinary and reproductive diseases: good to strong association with pyelonephritis, pelvic inflammatory disease, postabortal fever, and postpartum fever; moderate association with prostatitis, vaginitis, and cervicitis; weak association with Bartholin's gland abscess and involuntary infertility^{395,601}; and no association with nongonococcal urethritis, epididymitis, urinary calculi, Reiter disease, urethral syndrome, repeated spontaneous abortion and stillbirth, or chorioamnionitis.* With the exception of pelvic inflammatory disease and complications of pregnancy, which occur in adolescents, the other disease associations reported do not involve pediatric patients.

M. hominis has been recovered on two occasions from the CSF of a 2.5-year-old girl with a ventriculoperitoneal shunt.¹²¹² Because she had no complications from the infection and only minimal CSF inflammation, no treatment was initiated. Three months later, the organism could not be isolated from CSF and the child was doing well.

In volunteer studies in adults, researchers found that *M. hominis* could produce exudative pharyngitis.¹⁷³ Moffet and associates⁸¹⁴ isolated *M. hominis* from the throat of 1 of 174 infants and children with pharyngitis but made no similar isolation from a control group of children without pharyngitis. Neu and Ellner⁸⁶⁷ recovered *M. hominis* from the throat of 1 child in a group of 56 with exudative pharyngitis. Other *M. hominis* infections include septicemia in a 10-month-old burned infant,²⁵⁵ chronic multifocal osteomyelitis in an 8-year-old child,⁵¹¹ arthritis and vulvitis in a 4-year-old girl and 13-year old girl,⁴³ septicemia after heart surgery in a 5-year-old girl,²⁵⁴ severe pneumonia and pericarditis in a healthy 15-year-old girl,⁹²³ and exudative vaginitis in a 10-year-old girl.¹²⁰⁷ In one study, 10 patients with sickle-cell disease were found to have acute chest syndrome in association with *M. hominis* recovery from sputum or bronchoscopy specimens.⁸⁶⁸ A 4-year-old girl was found to have *M. hominis* endocarditis after biventricular repair of her congenital heart defect.²³⁸ Surgical wound infections, including to the brain and spine, have been due to *M. hominis*.^{634,972,1251}

In adult patients, the following clinical manifestations have been caused by *M. hominis*: rheumatoid arthritis⁴⁴; mediastinitis^{390,673,761,842};

endocarditis^{335,382,500,512,535,981}; isolated pericarditis in a lung transplant recipient⁶⁷⁹; hyperammonemia believed to be directly generated by *M. hominis*, resulting in fatal encephalopathy and sepsis in a lung transplant recipient¹²⁶⁴; pneumonia in a previously healthy man⁹⁹⁵; ICU-acquired infection in seven critically ill men³⁸⁸; soft tissue, cavity, spine, and meningeal infections at surgical sites^{142,354,498,624,672,805,1271}; parapharyngeal abscess after EBV infection⁵⁸⁷; brain abscess^{21,473,501,641,642,914,1298}; and bacteremia in a patient with multiple injuries.⁴⁴¹

Disease in the Neonate

Infants become colonized during passage through the birth canal, but such colonization tends to not persist. In a recent study of 208 women at delivery, *M. hominis* was recovered from cervicovaginal specimens in 11% and the gastric secretions of 1% of newborns.⁴²⁴ In prepubertal children, *M. hominis* only rarely is recovered from urine or genital specimens.

M. hominis also has been associated with neonatal pneumonia,¹¹⁷⁸ septicemia,¹⁵⁷ and meningitis in premature infants.^{468,1241} The Analyses of the Extremely Low Gestational Age Newborns study showed that infants born at less than 28 weeks' gestation with *M. hominis* recovered from the placenta were at an increased risk (odds ratio [OR], 2.5; 95% confidence interval [95% CI], 1.2–5.3) of later developing, emotional and behavioral dysregulation³⁷⁶ or attention deficit/hyperactivity problems (adjusted relative risk [RR], 2.3; 95% CI, 1.1–4.8).²⁸⁹ A review by Hata and colleagues⁴⁶² associated poor outcomes with delayed or infective initial therapy of *M. hominis* meningitis and presented a case in a premature infant that was successfully treated with moxifloxacin, promoting fourth-generation fluoroquinolones as an alternative treatment. A case was found of an infant sustaining birth-related eye injury who subsequently developed multiple subdural empyemas caused by *M. hominis*.²⁰³ Other systemic presentations include brain and scalp abscesses, ventriculitis, submandibular adenitis, abscesses of subcutaneous tissue, pericarditis, and conjunctivitis.^{1,409,558,802,944,993}

Differential Diagnosis

Illness caused by *M. hominis* infection rarely occurs in children. This organism should be considered an etiologic possibility in wound infections and a variety of illnesses in which routine cultures are negative. The possibility of *M. hominis* as an etiologic agent also should be considered in adolescent girls with urethritis or pelvic inflammatory disease.

MYCOPLASMA GENITALIUM

Properties

A thorough review by Taylor-Robinson and Jensen¹¹⁴² summarizes the recent characterization of *M. genitalium*. It is a pleomorphic organism most often found with a tapered end, giving it a flask or bottle shape. It has a length of 0.6 to 0.7 μm and a diameter of 0.3 to 0.4 μm at the broadest part and 0.06 to 0.07 μm at the tip. As in other mycoplasmas, the terminal rod-like structure is believed to play a role in motility, cytoadherence, and binary fission.

Colonies have the typical “fried egg” morphology on solid media. Growth is suppressed on *Mycoplasma* media containing thallos acetate, which is normally used to prevent bacterial contamination. In media containing phenol red and glucose, *M. genitalium* metabolism can be detected by a color change from red to yellow. *M. genitalium* does not metabolize arginine or urea.

M. pneumoniae is closely related to *M. genitalium* and is believed to contain all of the latter's open reading frames within its genome.⁴⁷⁸ Because of similarities in their antigens, cross-reactivity between the two can occur in serologic testing. The genome of *M. genitalium* (580 kb) is much smaller, however, which necessitates efficiency. Rather than encode gene regulators, it is believed to rely on DNA supercoiling,²⁸⁴ antisense RNA,⁷¹⁰ and environmental signals, such as osmotic stress¹²⁹² and temperature,⁸³⁹ to modify transcription. It is also able to produce unlimited variants of its genes through homologous recombination within its own genome and through gene exchange between different clones.^{134,524,730}

Epidemiology

Over recent years, *M. genitalium* has become recognized as an STI that causes NGU in men and is strongly implicated in several inflammatory

*References 101, 130, 156, 310, 311, 400, 442, 646, 911, 912, 983, 1052, 1100, 1143, 1170, 1171.

reproductive tract syndromes in women. A comprehensive review of the literature by McGowin and associates⁷⁸⁰ found a worldwide incidence of 7.3% and 2.0%, in high- and low-risk female populations, respectively. Rates of infection are not associated with ethnicity, gender, isolation site, or previous pregnancies in women^{659,982} but have occasionally been shown to be associated with younger age, thought to be related to sexual promiscuity and risky behavior.^{555,813} *M. genitalium* infection was shown to be significantly reduced in circumcised versus uncircumcised men (8.2% and 13.4%, respectively).⁷⁸⁸ Studies in the adult general population abroad have shown an asymptomatic carrier rate of 0.3% in Korea,⁶⁰¹ 0.6% in the United Kingdom,⁹⁸² and 1% in Japan,¹¹²⁷ whereas in a study by the University of Illinois, investigators reported that of the 52 male patients with *M. genitalium* in their patient population in Kenya (9.9% prevalence), all but one were asymptomatic.⁷⁸⁸

In addition, multiple studies have shown elevated coinfection rates of *M. genitalium* with HIV.^{394,555,762,854} It is unclear whether this relationship is pathologically significant or merely represents the elevated risk for multiple infections in people with high-risk sexual activity.^{738,1142} Reports are conflicting about whether infection with *M. genitalium* is associated with increased vaginal HIV shedding.^{394,742,780,853} A prospective study of women found that those positive for *M. genitalium* infection at that visit were 2-fold more likely to test positive for HIV at the next visit.⁷⁶² It has been proposed that inflammation caused by a high *M. genitalium* load may weaken defensive barriers and attract CD4 T cells to the area, facilitating HIV transmission.^{256,267,779,781} In a study of Kenyan women, those with a high but not low burden of *M. genitalium* were more commonly found to have HIV shedding.⁷⁴²

The organism also has been recovered from the respiratory tract of patients with pneumonia who were participating in an *M. pneumoniae* vaccine trial.⁶⁴ Patel and colleagues⁹²⁴ found that 9.1% of bronchoalveolar lavage fluid samples taken from a large pediatric population with chronic respiratory disease were PCR positive for *M. genitalium*.

Clinical Manifestations

As cases are often asymptomatic, the role of *M. genitalium* as a sexually transmitted pathogen was initially unclear and required careful characterization, including studies of disease in experimentally infected chimpanzees.^{1141,1167,1171} With the use of PCR, Jensen and associates⁵⁴⁷ presented evidence suggesting a causative role in some cases of NGU. *M. genitalium* is now generally accepted as an emerging STI⁷⁴⁰ and a cause of mucopurulent cervicitis in women^{267,739} and NGU in men.⁷⁹⁰ Recent studies estimate that it is the most common etiology of NGU after *C. trachomatis*, responsible for 10% to 30% of the cases.⁸¹⁸ In addition, *M. genitalium* infection has been strongly associated with endometritis, pelvic inflammatory disease, preterm birth and spontaneous abortion, and infertility in both men and women.^{95,395,447,703,741,778}

M. genitalium has been recovered from pediatric patients with pneumonia and chronic respiratory disease.^{64,924} Respiratory colonization has been shown to occur during neonatal passage though the birth canal for other mycoplasmas. Hematogenous spread of *M. genitalium* is also possible and has been postulated as the mechanism for cases of arthritis with this organism.^{1142,1168} A 29-year-old man with a lesion on the glans penis was PCR positive for *M. genitalium* and negative for *N. gonorrhea*, and developed symptomatic urethritis with discharge, inguinal lymphadenopathy, perianal intertrigo, aphthous lesions on the oral mucosa, and oligoarthritis in both ankles and the right elbow.²⁰⁵

Differential Diagnosis

M. genitalium presents most commonly as an STI causing pathology in the lower genital tracts of both men and women and a possible role in upper tract inflammation. It should be considered in the workup of adolescents with urethritis or pelvic inflammatory disease.

MYCOPLASMA FERMENTANS

M. fermentans originally was isolated from the genital tract of men and women over 50 years ago, but it has not been well established as a cause of genitourinary disease.^{989,1138,1167} Horie and colleagues did describe three cases of nonsexually acquired genital ulcers (Lipschütz ulcers) in young women with positive serology for *M. fermentans*, indicating

recent infection.⁴⁹⁰ Although it has been identified by PCR in the peripheral blood mononuclear cells and lymph nodes of HIV-infected patients^{465,576,631,1010} and was initially suspected as a cofactor in the development of AIDS,¹²¹⁵ it was also detected in the blood of homosexual men without HIV infection.^{576,631,733} In addition, it has been isolated from the respiratory tract, bone marrow, synovial fluid, and urine of healthy and immunocompromised patients.^{65,99,713,751,820,836,1215,1238,1253} Its membrane surface carries highly immunogenic proteins and phosphoglycolipids⁹⁸⁵ which could trigger inflammatory arthritic diseases, including rheumatoid arthritis.^{402,554,1083} A lipid-associated membrane protein from *M. fermentans* named macrophage-activating lipopeptide-2 (MALP-2) was found to be an extremely potent natural macrophage stimulator, comparable to LPS.^{383,832}

MYCOPLASMA PENETRANS

M. penetrans is a relatively newly recognized species originally isolated from the urogenital tract of patients with AIDS.^{711,712} In a seroprevalence study, Wang and associates¹²³⁰ found that 35.4% of HIV-infected patients had antibody to *M. penetrans* versus only 0.4% of HIV-seronegative subjects. They subsequently noted a high prevalence of antibody to *M. penetrans* in the sera of homosexual men but not in the sera of other HIV transmission groups.¹²³¹ In a more recent study, Grau and colleagues⁴²⁶ found that 18.2% of HIV-infected patients had antibody to *M. penetrans*, whereas only 1.3% of HIV-seronegative persons had antibody. *M. penetrans* antibody seroprevalence increased with progression of HIV-associated disease, and it was associated predominantly with homosexual practices in the HIV-infected patients. No pediatric data relating to *M. penetrans* seroprevalence are available.

DIAGNOSIS OF GENITAL MYCOPLASMAS

M. hominis, *U. urealyticum*, and *U. parvum* are ubiquitous in the genital tracts of normal persons and frequent colonizers of mucosal surfaces in infants; therefore, assigning causation of disease based on isolation is difficult. *M. genitalium* is now widely recognized as an STI, and culture or PCR for mycoplasmas is warranted in cases of urethritis when smears reveal polymorphonuclear neutrophils without organisms suggestive of gonococci. Isolation of these species from a normally sterile site or suppurative focus warrants further investigation, especially in newborns and others with weakened immune systems. The clinical significance of isolation of genital mycoplasmas from urine obtained by suprapubic bladder aspiration in infants remains to be determined.⁶⁹² In such instances, analysis of urinary sediment has been normal.

Because of their fastidious growth, these species cannot be identified by routine bacteriologic culture methods; therefore, specific culture for mycoplasma must be requested. Genital mycoplasmas may be isolated on special broth and solid media that are available commercially. Shepard 10B broth and A8 agar have been used successfully for cultivation.¹⁵⁷ A recent study comparing different culture specimens found that urethral swabs were more accurate (specificity, 99.9%; positive predictive value [PPV], 99.6%) than vaginal swabs (specificity 95.1%; PPV, 67%) or urine cultures (specificity, 96%; PPV, 75%) for detecting *M. hominis* in women with lower urinary tract symptoms, with similar numbers for *U. urealyticum*.⁵¹⁰

Cassell and colleagues^{153,157} recommended that mucosal specimens be obtained with a Dacron or calcium alginate swab and be placed in a specific mycoplasmal transport medium, such as Shepard 10B broth. Specimens should be refrigerated at 4°C (39.2°F) until they are transported to the laboratory and should be protected from drying. Alternatively, specimens in appropriate transport media can be frozen at -70°C (-94°F) because mycoplasmas are stable for long periods under these conditions. Specimens should be diluted serially in 10B broth to at least 10⁻³ (preferably to 10⁻⁵) to overcome any potential inhibitory substances or metabolites, and an aliquot of the original sample and dilution should be plated directly onto A8 agar. Body fluids (e.g., blood, CSF, and pleural fluid) should be inoculated into 10B broth in an approximate 1:10 ratio (usually 0.1 mL fluid/0.9 mL 10B broth). Blood should be collected free of anticoagulants. Broth cultures and agar plates are incubated under 95% nitrogen and 5% carbon dioxide. Cultures

generally become positive within 2 to 5 days. The presence of mycoplasmal growth in 10B medium is indicated by a change in color from yellow to pink, which is caused by an alkaline shift in the media as a result of either the urease activity of ureaplasmas or arginine hydrolysis by other *Mycoplasma* spp. Growth of mycoplasmas in broth culture, as indicated by a change in color, should be confirmed by inoculation of a broth specimen onto A8 agar. Characteristic colonies can be identified readily on A8 agar after 24 to 72 hours of incubation.

Serologic tests have been used to measure antibody to genital mycoplasmas. Such tests include the metabolic inhibition assay, enzyme-linked immunosorbent assay, mycoplasmacidal test, indirect hemagglutination, indirect immunofluorescence, and IgG and IgM immunoblotting.^{157,275,384,955} Because of the presence of maternal antibodies, as well as their own poorly functional immune system, use of these tests for establishing the diagnosis of mycoplasmal infection in infants remains problematic and is not well established. In these cases, diagnosis should rely on culture results and/or NAAT tests (PCR or transcription-mediated amplification).

PCR assays have become commercially available over recent years for detecting genital mycoplasmas.^{98,974,1105,1284} Comparison studies show that PCR is a more rapid and sensitive method of detection for genital mycoplasmas than culture. On endotracheal secretions, Blanchard and associates⁹⁸ reported finding a sensitivity of 100% and a specificity of 99% for *Ureaplasma* spp.

PCR assays involving the urease gene, 16S RNA genes, and multiple-banded antigen genes have been used to detect *Ureaplasma* spp.* PCR detection of 16S rRNA and ribosomal DNA targets of *M. hominis*^{6,425,724} and the 23S rRNA⁵⁴³ and 16S rRNA⁸⁰⁷ from *M. genitalium* are available in certain large medical centers and commercial laboratories, although they are not yet approved by the Food and Drug Administration (FDA) in the United States. Assays also exist that can screen for multiple *Mycoplasma*-related species simultaneously, using fluorescence polarization,⁶⁰ PCR-RFLPs,⁸⁰⁷ multiplex PCR^{783-785,1000} and oligonucleotide microarrays.⁵³⁶ Ultimately, these methods may aid in identifying colonized or infected infants more readily (results available in 1 day) and reliably, given the fastidious nature of these organisms and the scarcity of microbiology laboratories that routinely perform mycoplasmal culture.

OTHER MYCOPLASMA SPECIES AND MYCOPLASMA RELATIONSHIPS

Mycoplasma salivarium

M. salivarium is part of the normal human oral flora. It contains a very potent macrophage- and fibroblast-stimulating lipoprotein that can induce inflammatory reactions in gingival cells^{895,1112} and has been thought to occasionally play a role in oral and periodontal infections¹²³⁷; however, it has rarely been associated with disease in other sites of the body. Examples include arthritic joints, such as the knee of a 39-year-old woman with hypogammaglobulinemia,¹⁰⁷⁹ the knees of rheumatoid arthritis patients,⁵⁵⁴ the synovial fluid of patients (including a 15-year-old girl and 16-year-old girl) with temporomandibular joint disorders,¹²³⁸ a submasseteric abscess in an 84-year-old woman,⁴³⁶ and an empyema in a 39-year-old man with laryngeal cancer.⁶¹ The organism was also found in the polymicrobial biofilm of an occluded biliary stent in a 71-year-old man with liver cirrhosis.⁴⁷⁶

Mycoplasma pirum

M. pirum originally was recovered from eukaryotic cell cultures, and its origin was traced to a human tumor cell line.^{15,268,661} It has been recovered more recently from primary lymphocyte cells in patients with AIDS.⁹⁹

Zoonotic *Mycoplasma*

Mycoplasma spp. have been identified that infect a wide variety of birds, reptiles, fish, and mammals. Human infection with these species is rare but can occur when there is close contact, such as in veterinary medicine, animal training, hunting, fishing, and agriculture. There have been

reports of fishermen with open hand wounds or bites catching *Mycoplasma phocacerebrale* from seals. Commonly referred to as “seal finger,” this disease involves cellulitis of the affected area with eventual joint involvement if not treated.^{55,538,1249} One case of seal finger with a novel mycoplasma species caused disseminated infection and septic arthritis of the hip.¹²⁴⁷ Hemotropic mycoplasmas (also known as “hemoplasmas”) cause hemolytic anemia in many domestic and farm animals, and cases have been described of humans being infected through arthropod vectors associated with pigs, sheep, cattle, dogs, and cats.^{107,285,507,1119,1236,1290} In one case, a novel hemoplasma with no identified origin was found in a 60-year-old woman.¹¹⁰³ Coinfections with *Bartonella* spp. are not uncommon. Outbreaks of hemoplasmas in China have been described, including a high prevalence of congenital infection with severe disease.^{507,1275}

Acquired Immunodeficiency Syndrome–Associated Mycoplasmal Infections

The frequent identification of *M. fermentans*, *M. pirum*, and *M. penetrans* infections in HIV-infected patients led to the consideration that they may function as cofactors in the progression of HIV infection and immunodeficiency.^{99,496,628,820} Although these mycoplasmas have the capacity to invade cells and to be potent immunomodulators, their pathogenic role, if any, in association with HIV has not yet been determined. Studies on *U. urealyticum*, *M. hominis*, *M. salivarium*, and *M. orale* infection rates in HIV-positive and HIV-negative subjects showed no significant differences.^{176,653}

Mycoplasma and *Ureaplasma* Infections in Immunocompromised Patients

Patients with hypogammaglobulinemia are susceptible to severe persistent infection with *Ureaplasma* spp., *M. hominis*, *M. amphoriforme*, *M. pneumoniae*, *M. salivarium*, and *M. orale*.^{41,358,374,405,817,948,978,1079} Clinical manifestations include osteomyelitis, arthritis, cellulitis, and chronic respiratory tract illness. Patients need to be treated for prolonged periods with high-dose intravenous immunoglobulin and antibiotics to which the specific agents are susceptible. Severe and persistent infections also have occurred in liver, kidney, and bone marrow transplant recipients, as well as other immunocompromised patients.^{216,534,569,728,806,933,1087,1199}

Yechouron and associates¹²⁷⁸ reported a 64-year-old man with Hodgkin lymphoma who died of septicemia caused by *Mycoplasma arginini*, an animal pathogen. A similar case was described by Watanabe and colleagues.¹²³⁶ Three children with cancer had pneumonia in which bronchoalveolar lavage fluid specimens yielded *U. urealyticum*.¹³² Two of the patients died; the survivor's improvement coincided with erythromycin treatment. A pregnant woman with controlled congenital HIV infection and hypogammaglobulinemia secondary to lymphoma treatment developed severe pneumonia with effusions, in which pleural and lymph node samples were PCR positive for *M. hominis*.³⁴⁵ *M. hominis* infection has also been reported as a cause of septic arthritis in patients with hypogammaglobulinemia,^{1011,1265} septic arthritis in a 15-year-old girl 2 months after renal transplantation,⁷⁹⁹ osteomyelitis in a patient with Good syndrome,⁸⁸² and abdominal infection in a 9-year-old boy after liver transplantation.⁷²¹

Mycoplasma and Cancer

Mycoplasma invasion into human cells and subsequent chronic inflammatory processes have been proposed as potential mechanisms of tumorigenesis, alone or in conjunction with other oncogenic infections. Studies have attempted to link mycoplasma infections with prostate cancer, lung cancer, oral cancer, and lymphomas.^{141,314,925,977,1288,1291} Charles Rosser's laboratory has been able to induce malignant transformation of human prostate cells in vitro using mycoplasma.⁸⁵² Studies have also found an increased rate of *M. hominis* infection in patients with prostate cancer.⁶³ Studies in women with high-grade cervical dysplasia found that a majority were also infected with *Ureaplasma* spp. with or without *M. hominis*.³⁰⁶ Genital mycoplasmas have been considered an important cofactor for human papillomavirus infection.^{90,307,306} Also of concern is that some commensal mycoplasma species preferentially colonize neoplastic tissues and have been found to contain enzymes capable of inactivating certain chemotherapeutic agents.^{1183,1184}

*References 6, 7, 27, 98, 183, 202, 250, 724, 729, 865, 974, 1021, 1147, 1284.

Mycoplasma as a Cell Culture Contaminant

When *Mycoplasma* spp. were still first being recognized as human pathogens, they were also being studied as a prevalent and serious contaminant in the research and biopharmaceutical industries.³⁸ Because they are slow growing, pleomorphic, and resistant to β -lactams and other antibiotics frequently used to eliminate bacteria from cell culture media, contamination is often difficult to identify. Possible sources of mycoplasma include animal- and plant-derived raw materials in culture media and the skin from workers with poor aseptic technique. Fortunately, with better antibiotic options and rapid detection by PCR, these issues are resolving.^{753,1034}

TREATMENT OF GENITAL MYCOPLASMAS

Having no cell wall, mycoplasmas are naturally resistant to β -lactam antibiotics (i.e., penicillins, cephalosporins, monobactams, and carbapenems), polymyxins, sulfonamides, and vancomycin.^{113,1209,1210,1214} Although they may have moderate sensitivity to the aminoglycosides, the MICs of these agents for genital mycoplasmas usually are too high for therapeutic use. Tetracyclines and macrolides have been the drugs of choice, although because of concern for tetracycline toxicities and the comparative ease of taking a short course of azithromycin, the latter has come more into favor. Azithromycin is also seen as having the added benefit of treating both gonococcal and chlamydial genital infections when the etiology is not yet identified or could be polymicrobial. However, antibiotic resistance is growing, and some *Mycoplasma* spp. now require alternative regimens.²⁴⁰ Quinolones such as moxifloxacin and levofloxacin also have good activity against genital mycoplasmas and ureaplasmas,^{70,633,1126} but resistant variants have already appeared. When possible, antibiotic susceptibility testing should be performed on all clinically significant isolates. If the site of the mutation is known, high-resolution melt analysis^{1160,1173} or genetic amplification and sequencing^{544,1258} can be used to rapidly identify antibiotic resistance at the time of the initial diagnosis and eliminate the risk for treatment failure. These mutations can also be carried on plasmids or transposable genetic elements, sometimes conferring resistance to multiple groups of antibiotics.^{543,544,633,748,931,1050,1051,1124} Mutations in the 23S rRNA gene of genital mycoplasmas, just as in *M. pneumoniae*, are conferring widespread macrolide resistance. The discovery that genital mycoplasmas may also create biofilms, protecting them from antibiotic activity, further complicates therapy.³⁸⁹

Ureaplasma spp. have retained susceptibility to macrolides, doxycycline, tetracycline, and chloramphenicol. Resistance to ciprofloxacin is developing; however, oxifloxacin and moxifloxacin are still effective and better than levofloxacin.⁶³³ Historically, tetracycline has been used for empiric coverage in cases of NGU.^{453,484} However, due to adverse effects, erythromycin was considered a preferable alternative in children, and would also cover *Chlamydia* and *Ureaplasma*. Although still commonly used, erythromycin is less favored as a result of growing resistance⁶³³ and adverse effects. Cardiac toxicity, consisting of acute cardiorespiratory deterioration possibly secondary to cardiac arrhythmias, has been reported in neonates treated with intravenous erythromycin lactobionate for presumed ureaplasma pneumoniae.³²⁷ Ototoxicity has been seen in adults but not in neonates.²⁴⁶ Oral erythromycin has also been associated with hypertrophic pyloric stenosis in infants younger than 6 weeks.¹⁶³ Doxycycline has since become a preferred choice for ureaplasma infections, while also being effective against coinfection with *M. hominis* or gonorrhea.* First-line therapy for NGU is doxycycline 100 mg twice daily for 7 days. In cases of treatment failure due to resistant strains, 5-day therapy with azithromycin is advised.⁴⁹⁴ Azithromycin and clarithromycin are active in vitro against *Ureaplasma* spp.,^{584,991,1078,1208} but their use in neonates has not been evaluated thoroughly. When given orally to infants with very low birthweight colonized with *Ureaplasma* spp., serum levels of clarithromycin at a dose of 7.5 mg/kg every 12 hours were subtherapeutic.¹⁰⁰⁴ For this reason, a dose of 15 mg/kg every 12 hours is recommended. Although the exact duration of therapy is not known, a 10- to 14-day course seems reasonable

when clinical improvement and microbiologic eradication are observed during that period.

M. hominis has developed marked resistance to common macrolides, which are no longer recommended for treatment.^{991,1208} By contrast, 16-membered ring macrolides, such as josamycin and related lincosamides, have shown effectiveness against *M. hominis*. However, they have not been extensively studied and are not approved by the FDA in the United States.^{584,633,931,1300} Other therapies include chloramphenicol, clindamycin, rifampicin, quinolones (i.e., ofloxacin and moxifloxacin), and tetracyclines (doxycycline especially).^{70,613,1209} *M. hominis* is usually sensitive to tetracyclines; these antibiotics should be used if the benefits outweigh the risk for toxicity.^{113,139,1109,1136,1248} During the past decade, resistance of *M. hominis* to tetracycline itself has increased; however, doxycycline remains effective.^{249,633,766}

M. genitalium remains sensitive to macrolides and newer-generation quinolones, such as moxifloxacin.^{449,1099,1126,1148} A single 1-g dose of azithromycin has been a favored choice because it also treats both gonococcal and chlamydial genital infections when the etiology is not yet identified or could be polymicrobial. However, resistance of *M. genitalium* to azithromycin is becoming more common, with rates as high as 30% to 50% in some populations.^{443,872,1260} The United States and United Kingdom 2015 treatment guidelines^{494,1260} recommend 5-day dosing (500-mg dose followed by four 250-mg doses) over single-dose treatment, especially as some resistance mutations have been observed to develop de novo during therapy.^{28,112,204,325,443,544,658,1051} Others suggest extended regimens that include at least one dose that is 1 or 1.5 g to also ensure coverage of chlamydia, although this could reduce patient compliance.⁴⁹² Extended dosing with azithromycin has been found to be significantly more effective than even multidose doxycycline.^{28,96,789} Doxycycline efficacy is only 30% to 40%, and although the mechanism for its failure has not been identified, its use has not been found to promote resistance.^{493,1032,1260} Moxifloxacin (400 mg daily for 7–14 days) is highly effective in cases of azithromycin resistance, but moxifloxacin resistance is also beginning to appear.^{791,1050} Although not FDA approved, sitafloxacin²⁶⁶ and pristinamycin⁹² have been used to treat quinolone-resistant strains abroad, and solithromycin has been shown to be highly effective in vitro.⁵⁴⁵

Mycoplasmas are not susceptible to the antimicrobial agents routinely used to treat neonatal infections. The decision to cover for possible mycoplasma infection should be based on the clinical picture and culture results. In general, isolation of mycoplasmas from a normally sterile site in an ill neonate is an indication for consideration of treatment. The possibility of mycoplasma infection also should be suspected when a child appears septic and is not responding to standard antibacterial or antiviral therapy, and appropriate samples for mycoplasma culture or PCR assay should be obtained. However, no large randomized clinical trials have determined the efficacy of treatment in neonates. Experience on which to base treatment decisions, the choice of drug, and the duration of therapy is very limited.¹²²⁸

Isolation of mycoplasmas from endotracheal secretions is not diagnostic of pneumonia, and most of these infants do not require any antimycoplasmal therapy. However, if pneumonia is suspected and the infant's clinical condition is deteriorating, a trial of therapy may be indicated despite the unknown efficacy of treatment. Azithromycin has been used for its antiinflammatory properties to protect infants from BPD. However, the safety and efficacy of azithromycin in infants with very low birthweight has not yet been studied.

PREVENTION OF GENITAL MYCOPLASMAS

Tetracyclines and fluoroquinolones are contraindicated in pregnancy; therefore, erythromycin is often used to treat mothers with genital mycoplasma infection. However, one report found that erythromycin administered between 26 and 35 weeks' gestation to pregnant women colonized with *Ureaplasma* spp. was not effective in reducing adverse outcomes, such as preterm delivery, low birthweight, or premature rupture of membranes.³¹⁶ In the ORACLE I study,⁵⁹² in which the use of broad-spectrum antibiotics was evaluated in mothers with premature rupture of membranes, use of erythromycin was associated with prolongation of pregnancy, reduction in neonatal treatment with surfactant,

*References 69, 613, 633, 759, 995, 1010, 1069, 1189, 1209, 1218, 1300.

decrease in oxygen dependence at 28 days of age and older, fewer major cerebral abnormalities on ultrasonography before discharge, and fewer positive blood cultures. The ORACLE II study, which consisted of 6295 women with spontaneous preterm labor, intact membranes, and no evidence of clinical infection, showed that none of the trial antibiotics were associated with a lower rate of the composite primary outcome events than occurred in placebo recipients.⁵⁹³ Smorgick and associates¹⁰⁷⁸ reported on a woman with preterm labor at 27 weeks' gestation and amniotic colonization with *U. urealyticum*, treated with 3 days of ciprofloxacin that was changed to 7 additional days of erythromycin after developing an allergic pruritic reaction. This regimen failed to eradicate the organism, and she was switched to 10 days of intravenous clindamycin and oral levofloxacin. Although there was no further testing of amniotic fluid for infection, the patient was able to delay delivery for 6 weeks and the infant was healthy despite placental pathology revealing chorioamnionitis with acute funisitis. Vouga and coworkers¹²⁰² performed a retrospective analysis of 5377 women who were treated with clindamycin for *M. hominis* or *Ureaplasma* spp. infections in late pregnancy and found that they had reduced rates of premature labor and had newborns with fewer respiratory complications compared to uninfected, untreated patients. Because erythromycin therapy does not eliminate *Ureaplasma* spp. from the lower genital tract, it most likely also does not prevent neonatal ureaplasma colonization.⁸⁹¹ Smorgick and associates¹⁰⁷⁸ support that in cases of *Mycoplasma* spp., intraamniotic colonization remote from term, expectant management is possible and that fluoroquinolones, clindamycin, or both may be more effective than erythromycin.

The effect of erythromycin on prevention of neonatal disease has not been evaluated fully.³³ Administration of erythromycin to preterm infants whose mothers had *Ureaplasma* spp. in their lower genital tract reduced respiratory tract colonization but did not decrease the duration of supplemental oxygen therapy⁵⁵⁹ or chronic lung disease.^{111,729} Treating infants with very low birthweight who have respiratory tract colonization with *Ureaplasma* spp. to prevent chronic lung disease cannot be recommended at present.¹³³

With adolescent patients who test positive for genital mycoplasma infections, it is prudent to seek out and treat the sex partners whenever possible.

Classification of Fungi

David Bruckner

Fungal infections are an important and growing cause of morbidity and mortality. This is largely because of an expanding population of immunosuppressed individuals who serve as susceptible hosts, including persons with human immunodeficiency virus (HIV) infections, recipients of solid organ or hematopoietic stem cell transplants, and patients with hematologic malignancies, burns, and indwelling medical devices. Less than 50 of the more than 100,000 currently identified species of fungi are known primary pathogens in humans, but many fungal organisms previously thought of as contaminants in clinical specimens are now recognized as etiologic agents of disease under the right circumstances. The challenging task of the clinical microbiologist is to learn to recognize and correctly identify clinically relevant fungi to guide proper patient treatment.

Medically important fungi belong to the kingdom called Fungi.¹⁻⁷ These organisms are classified by their basic growth pattern as yeasts or molds. Yeasts are unicellular fungi that reproduce by budding (e.g., *Candida* spp.) or by fission (e.g., *Schizosaccharomyces pombe*). The buds produced by infectious yeasts, called blastoconidia, can form chains called pseudohyphae. Molds are multicellular fungi that grow by means of filamentous cell projections called hyphae. The nuclei in different cells may or may not be separated by characteristic crosswalls or septa.

Some medically important fungi change from a multicellular hyphal form in the natural environment or in vitro to a budding single-celled yeast form or spherule with endospores in tissue. These pathogens are known as dimorphic fungi and include *Blastomyces dermatitidis*, *Coccidioides immitis*, *Coccidioides posadasii*, *Histoplasma capsulatum*, *Paracoccidioides brasiliensis*, and *Talaromyces marneffeii* (formerly *Penicillium marneffeii*).

Fungi may reproduce sexually or asexually. The sexual form of growth is called the teleomorph, and the asexual form is called the anamorph. Some fungi have more than one name because the anamorph and teleomorph forms were described and named at different times without the connection between them being recognized. As a result, the teleomorph and the anamorph forms of the same fungus have different names. *Emerella nidulans*, for example, is the teleomorph for the anamorph, *Aspergillus nidulans*. Some teleomorphic fungi can produce more than one asexual form of propagation. *Pseudallescheria boydii* is the teleomorph of two anamorphs, *Scedosporium apiospermum* and *Graphium eumorphum*. These three names refer to the same organism. Although the sexual means of reproduction forms the basis of the taxonomy of fungi, the anamorph is usually obtained in culture, and the anamorph name typically is used in reports from a clinical microbiology laboratory.

Until recently, fungi were allowed to carry multiple scientific names based on the sexual (teleomorph) and asexual (anamorph) stages of their life cycle. In many cases, it was difficult to establish the relationship of these forms. With the use of molecular genetics, dual naming is no longer necessary. Beginning in 2013, the dual naming was no longer permitted, and only one name is now used for a fungus. The main criteria for classification are genetic rather than phenotypic.^{1,3-7}

The Kingdom Fungi is divided into eight phyla. The medically important fungi are contained within the phylum Ascomycota, phylum Basidiomycota, and what was previously named phylum Zygomycota, for which sexual spores and their mode of production form the main basis for classification. Accepted fungal scientific names are published by the International Code of Nomenclature for Algae, Fungi, and Plants (ICN). Accepted scientific name databases can be seen at

Mycobank (<http://www.mycobank.org>) and Species Fungorum (<http://www.speciesfungorum.org>). The phylum names and the type of sexual spore formed by its members are as follows:

1. Ascomycota (ascospores)
2. Basidiomycota (basidiospores)
3. Glomeromycota (zygospores)

Organisms previously assigned to the phylum Zygomycota have been divided among subphylum Mucormycotina and subphylum Entomophthoromycotina within the phylum Glomeromycota. Current fungal taxonomy and classification into phyla and subphyla is based on the mode of sexual reproduction and concordant multilocus DNA sequences. Asexual fungi with no known teleomorph phase, previously characterized as a separate formal group known as the Fungi Imperfecti, have been designated in the familiar phyla based on molecular phylogenetics. The taxonomic scheme depicted is based on various sources. The higher-level classification of kingdom Fungi was revised by Hibbett and colleagues in 2007.⁴

The basic taxonomic units are the species, and they are grouped into a hierarchical system that includes genera, families, orders, classes, and phyla. The categories may be subdivided (e.g., subphylum, subclass, suborder) to indicate degrees of relationship. Populations within a given species that have some characteristics in common may be set apart as tribes, varieties, or some other subset designation. Delineation of the zoopathogen *Ajellomyces capsulatus*, the teleomorph of *Histoplasma capsulatum*, is as follows:

Kingdom: Fungi

Phylum: Ascomycota (includes 80% of the medically important fungi)

Class: Ascomycetes

Order: Onygenales

Family: Onygenaceae

Genus: *Ajellomyces*

Species: *Ajellomyces capsulatus* (anamorph: *Histoplasma capsulatum*)

Variety (applies to the anamorph):

H. capsulatum var. *capsulatum*

H. capsulatum var. *duboisii*

H. capsulatum var. *farcininosum*

This chapter includes taxa known to contain medically important fungi. Classes, orders, and families not known to contain pathogens are omitted. More detailed information can be obtained by consulting the references.

Kingdom: Fungi

Phylum: Ascomycota (The teleomorph consists of ascospores borne in an ascus. The anamorph may be unicellular yeasts or multicellular molds. This group accounts for 50% of all described fungi and 80% of the medically important fungi. Molecular phylogeny studies have been used to define this group, even when a known teleomorph for a given anamorph has not been described.)

Subphylum: Saccharomycotina

Class: Saccharomycetes

Order: Saccharomycetales (Ascomata are absent, asci are formed singly or in chains, and yeast cells divide by budding or fission.)

Family: Saccharomycetaceae

Genus: *Candida*

Debaryomyces (teleomorph)

Kluyveromyces (teleomorph)

- Pichia* (teleomorph)
Clavispora (teleomorph)
Issatchenkia (teleomorph)
Saccharomyces (teleomorph)
 Subphylum: Pezizomycotina (>90% of Ascomycota are mold species)
 Class: Eurotiomycetes
 Order: Onygenales (ascomata are cleistothecia)
 Family: Arthrodermataceae (agents of tinea [ringworm])
 Genus: *Arthroderma* (teleomorph)
Microsporium (anamorph)
Trichophyton (anamorph)
Epidermophyton (anamorph)
Chrysosporium (teleomorph)
 Family: Onygenaceae (agents of endemic pulmonary mycoses)
 Genus: *Coccidioides* (anamorph)
 Family: Ajellomycetaceae
 Genus: *Ajellomyces* (teleomorph)
Histoplasma (anamorph)
Blastomyces (anamorph)
Emmonsia (anamorph)
Paracoccidioides (anamorph)
 Order: Chaetothyriales
 Family: Herpotrichiellaceae (agents of phaeohyphomycoses and chromoblastomycoses)
 Genus: *Capronia* (teleomorph)
Cladophialophora (anamorph)
Exophiala (anamorph)
Fonsecaea (anamorph)
Phialophora (anamorph)
Rhinocladiella (anamorph)
 Order: Eurotiales (ascomata are cleistothecia)
 Family: Trichocomaceae (contains the largest number of human pathogens)
 Genus: *Aspergillus* (anamorph)
Penicillium (anamorph)
Talaromyces (teleomorph)
Emericella (teleomorph)
Eurotium (teleomorph)
Neosartorya (teleomorph)
Paecilomyces (anamorph)
 Order: Ophiostomatales (ascomata are perithecia with long necks)
 Family: Ophiostomaceae
 Genus: *Ophiostoma* (teleomorph)
Sporothrix (anamorph)
 Class: Sordariomycetes
 Order: Hypocreales (ascomata are mostly perithecia)
 Family: Hypocreaceae (contains agents of mycoses)
 Genus: *Gibberella* (teleomorph)
Nectria (teleomorph)
Acremonium (anamorph)
Fusarium (anamorph)
Trichoderma (anamorph)
 Order: Microascales (ascomata are cleistothecia or perithecia)
 Family: Microascaceae
 Genus: *Pseudallescheria* (teleomorph)
Scedosporium (anamorph)
Microascus (teleomorph)
Scopulariopsis (anamorph)
 Order: Sordariales (ascomata are cleistothecia or perithecia; rarely pathogens; contains many of the teleomorphs of the anamorph genus *Fusarium*)
 Class: Dothideomycetes
 Order: Dothideales (ascomata are cleistothecia)
 Family: Dothioraceae
 Genus: *Aureobasidium* (anamorph)
 Family: Teratosphaeriaceae
 Genus: *Hortaea*
 Family: Davidiellaceae
 Genus: *Cladosporium* (anamorph)
 Family: Piedraiceae
 Genus: *Piedraia* (teleomorph)
 Order: Pleosporales
 Family: Pleosporaceae
 Genus: *Cochliobolus* (teleomorph)
Exserohilum (anamorph)
Setosphaeria (teleomorph)
Curvularia (anamorph)
Alternaria (anamorph)
Ulocladium (anamorph)
Lewia (teleomorph)
 Class: Pneumocystidomycetes (found as trophozoites, cysts, and intracystic bodies; originally considered members of the kingdom Protozoa)
 Order: Pneumocystidales
 Family: Pneumocystidaceae
 Genus: *Pneumocystis*
 Phylum: Basidiomycota (Teleomorphs are basidium-bearing basidiospores; anamorphs are yeasts or molds. Arthroconidia are propagules of some molds.)
 Class: Tremellomycetes
 Order: Filobasidiales
 Family: Filobasidiaceae
 Genus: *Filobasidiella* (teleomorph)
Filobasidium (teleomorph)
Cryptococcus (anamorph)
Trichosporon (anamorph)
Magnusiomyces (teleomorph)
 Class: Malasseziomycetes
 Order: Malasseziales
 Family: Malasseziaceae
 Genus: *Malassezia* (anamorph)
 Class: Agaricomycetes
 Order: Agaricales
 Family: Schizophyllaceae
 Genus: *Schizophyllum*
 Phylum: Glomeromycota (Teleomorphs consist of zygosporangia; anamorphs consist of sporangiospores within a sporangium.)
 Subphylum: Mucormycotina
 Order: Mucorales
 Family: Cunninghamellaceae
 Genus: *Cunninghamella*
 Family: Lichtheimiaceae
 Genus: *Lichtheimia*
Rhizomucor
 Family: Mucoraceae
 Genus: *Actinomyces*
Cokeromyces
Mucor
 Family: Rhizopodaceae
 Genus: *Rhizopus*
 Family: Saksenaaceae
 Genus: *Apophysomyces*
Saksena
 Family: Syncephalastraceae
 Genus: *Syncephalastrum*
 Subphylum: Entomophthoromycotina (formerly phylum Zygomycota)
 Order: Entomophthorales (agents of entomophthoromycoses)
 Family: Ancylistaceae
 Genus: *Conidiobolus*
 Order: Basidiobolales
 Family: Basidiobolaceae
 Genus: *Basidiobolus*
 Phylum: Microsporidia (unicellular organisms that are obligate spore formers and intracellular parasites invading host cells)
 Subphylum: Apansporoblastina
 Family: Enterocytozoonidae
 Genus: *Enterocytozoon*

Family: Nosematidae
Genus: *Nosema*
Vittaforme
Family: Encephalitozoonidae
Genus: *Encephalitozoon*
Subphylum: Pansporoblastina
Family: Pleistophoridae
Genus: *Pleistophora*
Trachipleistophora

Aspergillosis

William J. Steinbach

Aspergillus is a versatile organism that can cause a broad spectrum of disease, including invasive disease in profoundly immunocompromised patients, saprophytic disease in immunocompetent people, and allergic disease in atopic individuals. Invasive aspergillosis (IA) is the leading cause of death due to major invasive mycoses. The high incidence of IA likely reflects the increasing number of severely immunosuppressed patients, more intensive immunosuppressive therapies for graft-versus-host disease (GVHD) and rheumatologic diseases, increased use of mismatched or unrelated donor transplants, newer preparative regimens used to avoid rejection or relapse, and increases in early posttransplantation survival due to better control of bacterial and cytomegalovirus (CMV) infections.^{143,241}

ORGANISM

Established by the Italian botanist Pier Antonio Micheli in 1729, the genus *Aspergillus* was created to accommodate an asexual fungus that produces spores (i.e., conidia) in chains or columns radiating from central structures. As a priest, Micheli recognized the resemblance of the spore-forming structures to that of the aspergillum, the liturgical instrument used to sprinkle holy water during the Catholic Mass and therefore applied the name *Aspergillus* to the fungus. More than 100 years later, *Aspergillus fumigatus*, the most important pathogenic species of the genus, was named by Fresenius because it looked like a puff of smoke.

The role of aspergilli in human disease was first recognized by Virchow in 1856.²³⁷ Virchow noticed the similarity between the aspergilli described from cases of animal infections and those he had observed in human disease. IA was recognized by Rankin in 1953, when he reported disseminated aspergillosis in a patient with aplastic anemia.¹⁸⁷ For the subsequent 60 years, the number of cases of IA increased substantially due to a rise in the number of immunocompromised patients.

The genus *Aspergillus* is characterized by the formation of flask-shaped or cylindrical phialides in a single or double series on the surface of a vesicle at the apex of a conidiophore.¹⁸⁸ Conidia are deciduous and globose, oblong to elliptical, and various colors.

In 1926, Thom and Church assembled all available information on *Aspergillus* in a monograph.²²¹ In 1965, Raper and Fennell expanded this work by adding many new species and provided descriptions of the species classified into 18 informal groups.¹⁸⁸ In 1985, Gams and colleagues revised the groups and assigned them to 18 sections as a formal taxonomic status.⁷⁸ Currently, there are approximately 250 species

assigned to 17 sections in the family Aspergillaceae,¹⁰⁰ and this number will continue to grow as new species are described.

Most human disease is primarily caused by *A. fumigatus*, *Aspergillus flavus*, *Aspergillus niger*, *Aspergillus terreus*, and *Aspergillus nidulans*. The classification of the genus *Aspergillus* has been revised from the original taxonomy to incorporate phenotype, morphology, and newer molecular approaches; consequently, the taxonomy remains dynamic.¹⁹⁵ *A. fumigatus* causes approximately 70% to 80% of cases of IA,²⁰⁹ but it is difficult to differentiate from the other closely related species based solely on morphology. *A. fumigatus* is responsible for most pulmonary disease, and most isolated sinus disease is caused by *A. niger* and *A. flavus*.¹⁸² Specific determination of the species of *Aspergillus* is clinically important for therapeutic reasons (e.g., antifungal resistance). For example, a review of *Aspergillus* cultures found that *A. terreus* was seen in only 3% of isolates in cases of IA, but it was found exclusively in cases of invasive disease (i.e., no cases of colonization).¹⁸²

Aspergillus is a ubiquitous organism, but its ecologic niche is the soil, where it functions as a saprophytic fungus growing on organic debris and recycling carbon and nitrogen.²⁵⁴ A classic sexual stage has been identified for *A. fumigatus*,¹⁷⁰ but the clinical relevance is unclear. Asexual reproduction is abundant and characterized by the production of green-pigmented, echinulate, asexual conidia (i.e., spores). *Aspergillus* aerosolize conidia, which immunocompetent people asymptotically breathe every day; most people inhale several hundred *A. fumigatus* conidia each day.⁸⁴ Infection in immunocompromised patients is usually acquired through inhalation of airborne conidia.

Two lines of host defense exist against *Aspergillus*—macrophages and neutrophils—and it appears that both are required for resistance to invasive disease. First-line defense is offered by alveolar macrophages, and in vitro murine studies have suggested that resident pulmonary macrophages are responsible for eliminating inhaled *Aspergillus* conidia from the lung.^{198,199} If conidia escape this defense mechanism, they develop into invasive *Aspergillus* hyphae and become susceptible to neutrophil killing by the release of toxic reactive oxygen species. The host can develop disease because of neutropenia, high-challenge doses of conidia that overcome macrophages, or corticosteroid suppression of macrophage conidiacidal activity.⁶³

A. fumigatus is particularly successful at causing invasive disease in immunocompromised patients due to characteristics such as thermotolerance, small and abundant pigmented conidia, fast growth rate, production of toxic secondary metabolites, and numerous enzymes involved in breaking down complex polysaccharides. The ability to grow at 37°C

is crucial for the development of human disease. Although some *Aspergillus* species can grow at this high temperature, it has been reported that *A. fumigatus* can survive at temperatures up to 75°C, and this thermotolerance is likely a major factor in its ability to cause human disease.²³

Conidia are 2.5 to 3 µm in diameter, and this small size allows them to remain buoyant in the air for prolonged periods and to be inhaled deep into the lung alveoli. When inhaled by an immunocompetent person, conidia rarely have deleterious effects because they are cleared by phagocytic cells of the innate immune system. However, severe allergic disease can occur with repeated exposure to large doses of conidia or in atopic individuals.

Pigments found on the conidial surface are thought to play important roles in mediating the effects of damaging reactive oxygen species produced by phagocytic cells.¹⁸⁵ Mutants of *A. fumigatus* that lack these conidial pigments are more susceptible to killing by alveolar macrophages than their pigmented counterparts.¹²⁵ Whole-genome sequencing of several *Aspergillus* species has revealed that the fungi contain large numbers of enzymes involved in degrading complex polysaccharides.⁷⁷ The enzymes allow *Aspergillus* species to be enormously successful as saprophytes and contribute to their ability to cause invasive disease.

Species of *Aspergillus* are known for their production of secondary metabolites, including aflatoxin, which is produced by some strains of *A. flavus*. Although aflatoxin is extremely carcinogenic, its role in the development of human mycoses has not been thoroughly examined. Various putative *Aspergillus* virulence factors have been exhaustively reviewed,¹²⁸ and earlier gene-disruption studies examined proteases, toxins, hemolysins, melanin pigmentation, and other gene products with little success. The virulence of *A. fumigatus* likely depends on a combination of many attributes.

CLINICAL PRESENTATIONS

Aspergillus species are uncommon among pathogens because they are responsible for a gamut of infections, including primary allergic reactions, saprophytic involvement, and invasive disease.¹⁴⁵ The type of *Aspergillus* infection typically depends on the immunologic background of the infected host. Immunodeficient patients develop invasive disease, and immunoreactive patients develop allergic disease. The most frequently encountered presentations involve the lungs, such as allergic broncho-pulmonary aspergillosis (ABPA) and acute or chronic invasive pulmonary aspergillosis (IPA). Other common infections include invasive acute or chronic sinusitis, cutaneous aspergillosis, aspergilloma, and cerebral aspergillosis.^{49,145} The clinical manifestations of these infections in immunocompromised patients can be subtle and nonspecific, and they commonly occur late in the course of disease. A high index of suspicion must be maintained to ensure treatment in the early stages of disease. Unfortunately, the patients most vulnerable to *Aspergillus* infections are the least likely to display significant symptoms, adding to the difficulty of diagnosis.⁴⁹

Invasive Pulmonary Aspergillosis

Aspergillus species are ubiquitous in the environment, and a major portal of entry is the respiratory tract. In some immunocompetent patients, inhalation can result in nonpathogenic saprophytic colonization, but in the immunocompromised patient, conidial acquisition likely results in establishment of invasive disease.²²⁴ IPA is the most frequently documented form of IA, and it contributes considerably to morbidity and mortality among high-risk patients.⁵³ In a systematic review of the literature regarding the case-fatality rate of aspergillosis, 70% of infections were found to be invasive pulmonary disease.¹³⁰

As with other forms of *Aspergillus* infections, the burden of IPA is sustained by immunocompromised patients, including those who have undergone hematopoietic stem cell transplantation (HSCT), solid organ transplant (SOT) recipients, cancer patients, patients with various congenital immune deficiencies such as chronic granulomatous disease (CGD), and patients treated for autoimmune diseases with immune modifiers.¹⁹²

The clinical manifestation of IPA is heterogeneous; it can include fever unresponsive to broad-spectrum antibiotics, dry cough, shortness

of breath, pleuritic chest pain, hemoptysis, and pulmonary infiltrates on radiography.⁷ Although neutropenic patients more commonly have fever at presentation, for about 20% of patients (i.e., those receiving high-dose corticosteroid therapy), fever and cough are not evident for the first several days of infection.^{98,145} Disease often manifests as bilateral, diffuse pulmonary infection, and dyspnea is a common presentation for these patients. Progression of infection is characterized by invasion of small vessels that causes hemoptysis, a leading symptom of IPA in some neutropenic patients. Two patterns of hemorrhage may be identified: hemorrhagic infarction due to vascular invasion and formation of mycotic aneurysms during recovery from neutropenia, which can rupture and cause fatal hemoptysis.¹⁵⁹

Although cancer patients undergoing treatment account for most of those at risk for *Aspergillus* infections, IPA is the leading cause of death for another, largely pediatric patient population with underlying chronic granulomatous disease (CGD). Patients with CGD have an estimated 33% lifetime risk of IA, and IPA can be the first manifestation of CGD. Whereas disease in most patient groups is caused by *A. fumigatus*, most cases of *A. nidulans* infection have affected patients with CGD.⁴⁰ In one review, *A. nidulans* occurred in six patients with CGD but did not occur in any other patient group.²⁰² Although *A. fumigatus* was more common than *A. nidulans* in CGD patients, infection with *A. nidulans* was significantly more likely to be refractory to antifungal therapy and result in dissemination and death.

In addition to the epidemiologic variations of specific *Aspergillus* species, the clinical presentations of patients with CGD can be different from those of neutropenic patients. Unlike the acute, rapidly progressive illness described for other immunocompromised patients, the clinical course of patients with CGD is characterized by an insidious onset of fatigue, fever, increased sedimentation rate, and pneumonia.²⁰² The diagnosis for a patient with CGD often does not contain typical clinical symptoms (including no symptoms) and may consist of only an elevated erythrocyte sedimentation rate in the setting of no fever. In early-stage disease, there is an acute neutrophilic response in which the neutrophils surround hyphae. However, in patients with CGD, the hyphae remain intact due to impaired neutrophil-mediated killing. In this setting, IPA in a patient with CGD is a chronic, progressive infection that can spread locally to involve pleura, vertebrae, and the chest wall.

Aspergillus osteomyelitis involving a rib, vertebra, or femur is a common presentation for patients with CGD, but it is not commonly seen in other patient populations.⁶⁵ Thoracic wall extension of pulmonary IA has been reported.²⁵³ In a study of 24 cases of osteomyelitis caused by *Aspergillus* species in 22 CGD patients, 14 isolates (58%) were caused by *A. nidulans*, and 10 were caused by *A. fumigatus*.⁶⁶

In contrast to patients with neutropenia, hyphal angioinvasion is not a feature of disease in patients with CGD. The halo sign (i.e., angioinvasion with surrounding tissue ischemia), cavitated lesions, and pulmonary infarcts are not typical in patients with IA and CGD.

Invasive Aspergillus Sinusitis

Fungal sinusitis can manifest as allergic, saprophytic, or invasive disease. Invasive *Aspergillus* sinusitis is likely underdiagnosed because of its variable clinical presentation and difficulty in establishing the diagnosis,^{49,98,145} possibly due to a decreased inflammatory response in affected patients. Patients can have nasal congestion, discharge, headache, facial pain or swelling, and abnormal nasal cavity findings such as pallor of the nasal septum or turbinate mucosa. Patients also can have epistaxis, orbital swelling, and high fever.¹⁶¹

A definitive diagnosis can best be established by endoscopic evaluation and selective biopsy. Common findings on endoscopy include pallor of the mucosa, discoloration or granulation of the mucosa due to ischemia from angioinvasion, and as the disease progresses, a blackened necrotic focus can be found (Figs. 198.1 and 198.2). Extension into bony structures can occur at the site of necrosis, spreading disease into adjacent structures such as the orbit and the brain, which carries a high mortality rate.

Although imaging is not diagnostic, it can aid in establishing the diagnosis because it can be used as a roadmap for endoscopy by identifying the involved sinuses (Fig. 198.3). In a review of 25 patients with rhinosinusitis, 44% showed evidence of invasion beyond the sinus cavities

FIG. 198.1 A 12-year-old with acute myelogenous leukemia and unrelated cord blood transplant developed *A. fumigatus* sinusitis. Endoscopy shows classic pale mucosa.

FIG. 198.2 In the same patient as in Fig. 198.1, endoscopy shows necrotic mucosa at the basilar skull area.

on computed tomography (CT).⁸² In the same study, however, 12% of patients had negative CT scans, emphasizing the need for physicians to have a high index of clinical suspicion in making the diagnosis to ensure the best outcome.

Cerebral Aspergillosis

Aspergillus infections most commonly involve the lungs, but disease can disseminate through the bloodstream and involve distant organs. The central nervous system (CNS) is a common site of dissemination.⁸⁷ Cerebral aspergillosis may result from direct extension through the sinuses. Studies have estimated that CNS aspergillosis may be found in 40% to 50% of patients with IA and acute leukemia or allogeneic HSCT.^{105,197} As with other *Aspergillus* infections, *A. fumigatus* is the most frequently encountered species in cerebral aspergillosis, although *A. flavus*, *A. niger*, and *A. nidulans* also have been implicated.¹⁰⁶

The clinical presentation often does not include classic symptoms for an intracranial process such as headache, nausea, or vomiting. Patients instead have mental status alterations, convulsions, hemiplegia or hemiparesis, ophthalmoplegia, and loss of consciousness. Severely immunocompromised patients may not display these symptoms, and disease progresses more rapidly.

Aspergillus hyphae are angioinvasive and thrombose arteries to create hemorrhagic infarcts. CNS aspergillosis can manifest as solitary or multiple abscesses or, less commonly, as mycotic aneurysms and carotid artery invasion. Cerebral aspergillosis can also appear as meningitis or

granuloma.¹⁰⁶ Cerebral aspergillosis is seen as multiple areas of low density and no enhancement even with contrast on CT, and lesions are usually located within the basal ganglia and gray-white matter junction. On magnetic resonance imaging (MRI), these abnormalities appear as foci of an intermediate T2-weighted signal surrounded by a rim of higher signal intensity.^{171,223}

Because aspergillosis of the CNS carries a case-fatality rate of almost 90%,¹³⁰ prompt diagnosis and treatment are key to survival. Unfortunately, a definitive diagnosis requires biopsy, and these patients typically are too coagulopathic to undergo the procedure.

Cutaneous Aspergillosis

Neonates, burn victims, HSCT recipients, SOT recipients, and other immunocompromised patients most frequently develop cutaneous aspergillosis. Cutaneous *Aspergillus* infection has a reported incidence between 4% and 11%.^{48,248}

Cutaneous aspergillosis can be primary, as is more often seen in children as a result of skin injury or traumatic inoculation, or secondary, occurring as hematogenous spread or extension from infected underlying structures.²²⁸ Primary cutaneous aspergillosis has been associated with intravenous access devices, adhesive dressings, and sites of burns or surgery. Although cutaneous aspergillosis is rare, premature infants are at particular risk because their skin is immature and vulnerable. HSCT recipients usually develop disease as a result of secondary hematogenous seeding from a primary source, usually the lungs.

FIG. 198.3 In the same patient as in Figs. 198.1 and 198.2, computed tomography shows complete opacification of the right maxillary sinus.

Lesions often begin as erythematous, indurated papules that progress to ulcerative, painful, and necrotic lesions.²¹³ Treatment involves debridement and excision of necrotic tissue, which provides diagnostic material, and the use of systemic intravenous antifungals and topical preparations. Because cutaneous aspergillosis often heralds underlying, undiagnosed systemic disease, relying on topical antifungal coverage alone is likely inadequate.

Chronic Aspergillosis

Chronic aspergillosis is an important and distinct entity from IA. It typically affects immunocompetent or less immunocompromised patients, although some degree of immune suppression usually exists, and exposure to corticosteroids is common. Patients often have underlying pulmonary disease, such as cavitary tuberculosis, sarcoidosis, emphysema, or fibrotic lung disease.

The 2016 clinical guidelines for chronic pulmonary aspergillosis include consensus approaches to diagnosis and management.⁵¹ Five categories are used to describe chronic pulmonary aspergillosis, and each has significantly overlapping clinical features: aspergilloma, chronic cavitary pulmonary aspergillosis (CCPA), chronic fibrosing pulmonary aspergillosis (CFPA), *Aspergillus* nodule, and subacute IA, which was previously called chronic necrotizing or semi-IA.

Diagnosis of chronic pulmonary aspergillosis requires a specific appearance in thoracic imaging (preferably CT), direct evidence of *Aspergillus* infection or an immunologic response to *Aspergillus*, exclusion of alternative diagnoses, and disease lasting for at least 3 months. If a fungal ball is observed, diagnosis requires only a positive assay for *Aspergillus* immunoglobulin G (IgG) or precipitins or the finding of *Aspergillus* in a bronchoscopic specimen. Due to the ubiquitous nature of *Aspergillus*, a positive sputum culture alone is not diagnostic.

Aspergillomas consist of a mass of tangled hyphae, cellular debris, fibrin, and few inflammatory cells. They develop as a complication of existing cavitary lesions and are typically found in the upper lobes, where there is poor drainage.^{145,224} The cavitary lesions can be caused by tuberculosis infection, sarcoidosis, bullous emphysema, and other diseases associated with cavitary lung lesions. *A. fumigatus* typically causes pulmonary aspergilloma. Although some patients remain asymptomatic, many have recurrent hemoptysis. The earliest radiographic sign is pleural thickening of a preexisting lung cavity. As the fungal ball develops, CT or plain radiography shows a solid, round, radiolucent

intracavitary mass that is separated from the thickened wall by a crescentic volume of air (i.e., air crescent sign).⁸⁶

Aspergilloma is a late manifestation, formed by the collapse of the fungal growth inside the cavity. Aspergillomas are designated as simple or complex based on radiologic criteria. The simple aspergilloma is a single cavity containing a fungal ball. Simple aspergillomas lack constitutional symptoms, paracystic lung opacities, cyst expansion, and progressive pleural thickening.¹¹³ Serologic or microbiologic evidence implicates *Aspergillus* in immunocompetent patients with minor or no symptoms and no radiologic progression during at least 3 months of observation.

CCPA, previously called complex aspergilloma, is the most common form of chronic pulmonary aspergillosis. Multiple pulmonary cavities form and expand, and they may or may not contain solid or liquid material or a fungal ball. A positive *Aspergillus* IgG antibody test or microbiologic evidence implicates *Aspergillus* spp. as the cause. To meet the diagnostic criteria, significant pulmonary or systemic symptoms and overt radiographic progression (i.e., new cavities, increasing pericavitary infiltrates, or increasing pleural thickening) should be observed over at least 3 months. Left untreated, the cavities enlarge and coalesce.

A fungal ball seen on chest imaging supports the diagnosis of chronic pulmonary aspergillosis in the form of a single aspergilloma or CCPA. Confirmation is provided by *Aspergillus* IgG testing,^{20,174} and the two forms are differentiated on the basis of symptoms and radiologic appearance. However, most CCPA patients do not have a fungal ball but instead have multiple empty cavities or cavities with an irregular internal wall with associated pleural thickening and pericavitary infiltrates. Most patients have negative results for sputum cultures. *Aspergillus* polymerase chain reaction (PCR) is more sensitive,⁵⁵ and bronchoalveolar lavage galactomannan (GM) testing is preferred over serum GM evaluation for diagnosis.⁵¹ Biopsy of the wall of a cavity in cases of CCPA yields chronic inflammatory cells and fibrosis, sometimes with granulomas. Hyphae consistent with *Aspergillus* spp. are usually seen adjacent to the cavity wall, but they are not invasive. Percutaneous aspiration of a cavity with a positive *Aspergillus* culture is an alternative means of establishing the diagnosis. More than 50% of patients have an increased total and *Aspergillus*-specific IgE titer, and eosinophilia may be detected.²⁷

CFPA, which is characterized by progression of the cavities to extensive pulmonary fibrosis is an end-stage complication of CCPA. It is severe fibrotic destruction of at least two lobes of the lung that complicates CCPA and causes major loss of lung function. Fibrosis usually manifests as a consolidation on imaging, but large cavities with surrounding fibrosis may be seen. Thoracic imaging usually shows one or more *Aspergillus* nodules (<3 cm in diameter) that do not cavitate. Tissue invasion is lacking, but necrosis may be seen.

Subacute IA was previously called chronic necrotizing pulmonary aspergillosis (CNPA), subacute IPA, or semi-IPA. It is an indolent pulmonary infection of patients with mild or moderate immune dysfunction, such as after prolonged corticosteroid use or after resolution of neutropenia.¹⁴⁵ Subacute IA is more progressive than CCPA.

Clinical signs of subacute IA include cough, fever, fatigue, and weight loss. At presentation, patients often have pulmonary and general symptoms. Hemoptysis, shortness of breath, and productive cough are typical, but fever and chest pain are uncommon.²⁷ Patients are often mistakenly thought to have tuberculosis.

Allergic Bronchopulmonary Aspergillosis

ABPA occurs in asthmatic and cystic fibrosis (CF) patients. It is a pulmonary disease caused by type I and III hypersensitivity reactions to *A. fumigatus* allergens. Exposure and inhalation of *Aspergillus* conidia results in saprophytic (noninvasive) colonization of the bronchial airways, which triggers an IgE-mediated allergic inflammatory response. Over time, bronchial obstruction takes place, and patients develop productive cough, wheezing, and chest pain. Fever and malaise are other presenting symptoms.²¹⁴

Diagnosis is based on eight primary criteria: history of bronchial obstruction (e.g., asthma), peripheral blood eosinophilia, elevated total serum IgE levels, serum IgE antibodies specific to *A. fumigatus*, immediate (type I) skin test reactivity to *Aspergillus* antigen, serum precipitin (specific IgG) antibodies to *A. fumigatus*, pulmonary infiltrates, and

central bronchiectasis, often with peripheral tapering of the bronchi. The 2016 international consensus–proposed diagnostic criteria for ABPA included a predisposing condition (i.e., bronchial asthma or CF) and two obligatory criteria: a type I *Aspergillus* skin test positive result or elevated IgE levels against *A. fumigatus* and an elevated total IgE level. Two of three other required criteria include precipitating or IgG antibodies against *A. fumigatus* in serum, radiographic pulmonary opacities consistent with ABPA, and a total eosinophil count greater than 500 cells/ μ L in a steroid-naïve patient.⁵¹

Radiologically, ABPA is characterized by bronchial wall thickening, pulmonary infiltrates, and central bronchiectasis, a result of the type III hypersensitivity reaction.^{145,224} The diagnosis of ABPA in CF patients is difficult because many of the diagnostic criteria overlap with common manifestations of CF. In asthmatic patients, ABPA manifests as poorly controlled asthma, pneumonia that represents mucoid impaction, persistent eosinophilia, and bronchiectasis or with chronic pulmonary aspergillosis and lung fibrosis. In CF patients, ABPA manifests as exacerbations that are difficult to control.

EPIDEMIOLOGY

Aspergillus is ubiquitous in the environment. *Aspergillus* species are estimated to be responsible for more than 200,000 cases of IA annually, and global burdens suggest that more than 1.2 million patients have chronic pulmonary aspergillosis and 4.8 million patients suffer from ABPA.^{50,56}

Those at risk for IA include patients with prolonged neutropenia, HSCT recipients, SOT recipients, patients receiving corticosteroids or other immune modifiers, and patients with CGD. In patients with hematologic malignancies, myelodysplastic syndrome, and other diseases associated with marrow failure (e.g., aplastic anemia), the intensity and duration of neutropenia predict the risk of IA.^{81,251} Patients with refractory or relapsed acute leukemia treated with reinduction regimens are at particularly high risk for IA. In SOT recipients, the intensity of immunosuppression to prevent or treat allograft rejection, colonization, and coinfection with CMV influence the risk of IA. Lung transplant recipients have one of the highest risks of IA,^{163,175} and one half of these cases of IA occur 1 year or more after transplantation.⁶⁴ Pretransplantation *Aspergillus* airway colonization is common among CF patients, and it increases the risk of IA after lung transplantation.¹³²

IA also has been recognized in critically ill patients without traditional risk factors. One retrospective analysis¹⁵¹ identified 127 patients of 1850 (6.9%) admitted to the intensive care unit (ICU) with evidence of *Aspergillus* infection; however, only 5 of these patients had proven IA without predisposing host factors. Nonclassic factors include chronic obstructive pulmonary disease (COPD) and cirrhosis,^{24,150} and IA can follow other major infections, including influenza.^{127,250}

IA was the most common invasive mold infection in a review of approximately 5500 patients who underwent HSCT; among the more than 7% of HSCT recipients who had mold infections, *Aspergillus* infections were the most common, followed by *Fusarium*, *Zygomycetes*, and *Scedosporium* infections.¹⁴³ The incidence of *Aspergillus* infection among HSCT recipients is 3% to 7%,^{153,255} but the true incidence likely depends on many factors. In one study of HSCT recipients with IA, the risk of developing the disease was 12.8 times higher among recipients of allogeneic than autologous HSCT.¹⁶⁷ A retrospective review of 409 patients showed that 13.1% had IA, which represented 17.2% of all isolated pathogens for allogeneic transplant recipients and 3.8% for autologous transplant recipients.¹²⁰

Allogeneic HSCT recipients have three periods of risk for IA: neutropenia after the conditioning regimen, exogenous immunosuppression for treatment of acute GVHD, and exogenous immunosuppression for treatment of chronic GVHD (i.e., day 100+ after transplantation). The level of allogeneic donor and recipient human leukocyte antigen (HLA) disparity is the major determinant for GVHD severity and intensity of immunosuppression needed to control GVHD, which is the major predisposing factor for IA. T-cell–depleted or CD34-selected stem cell products can increase the risk of IA.^{142,227}

The well-characterized bimodal distribution of aspergillosis among HSCT recipients correlates with pre-engraftment neutropenia (median,

16 days after transplantation) and the peak of GVHD (median, 96 days after transplantation).²³⁹ This distribution likely reflects the two major mechanisms of protection against IA: alveolar macrophages and granulocytes. Most patients (86%) with autologous transplants were diagnosed with IA while neutropenic, whereas patients with allogeneic transplants were at greatest risk after engraftment or during impairment of cell-mediated immunity due to CMV or GVHD.²³⁹ In large reviews of patients undergoing allogeneic HSCT, the mean time to IA diagnosis was 88 to 115 days after transplantation,^{147,167,191,197} and the mortality rate exceeded 80%.

A large, prospective French study analyzed 424 cases of IA and found an incidence of 0.9% among autologous and 8.1% among allogeneic HSCT patients, respectively,¹³¹ highlighting a consistent finding that IA occurs much more readily in allogeneic HSCT recipients. Among SOT recipients with IA, the highest incidence of IA was for heart transplant recipients (4.8%), followed by lung recipients (4.1%), and significantly dropping for liver (0.8%) and kidney recipients (0.3%). These findings have been consistent in most larger studies. However, most patients with IA had a hematologic malignancy. The largest group had acute leukemia (35%), and the second largest group had chronic lymphoproliferative disorders (22%). For those with acute leukemia, IA occurred in 68% during the induction phase of chemotherapy, when the cytotoxic agents used typically are most intense, and in 27% during the consolidation phase.

The time to developing IA after transplantation was similar in different settings, with 68% diagnosed more than 100 days after HSCT and 18 of 27 SOT recipients with IA diagnosed at least 100 days after transplantation. Multivariate analysis showed factors independently associated with increased risk of death included older age, diagnosis based on positive culture with two positive GM assays, and pleural effusion or CNS involvement. The mortality rate for patients with acute leukemia was 38%, and allogeneic HSCT recipients had a staggering 56% overall mortality rate.

The Transplant-Associated Infection Surveillance Network (TRANSNET) study sponsored by the Centers for Disease Control and Prevention evaluated HSCT and SOT recipients from 23 US medical centers (2001–05) and included assessment of a total of 642 cases of IA.¹⁵ The 12-month cumulative incidence of IA for all HSCT recipients was 1.6%, compared with 0.63% for SOT recipients. The 12-week all-cause mortality rate was 57.5% for HSCT recipients and 34.4% for SOT recipients. Multivariable analysis demonstrated that neutropenia, renal insufficiency, hepatic insufficiency, early onset (<30 days) IA, proven IA, and methylprednisolone use (often for GVHD) were independently associated with mortality. Analysis for SOT recipients revealed that hepatic insufficiency, malnutrition, and CNS disease were independently associated with an increased risk of death. Among HSCT and SOT recipients, receipt of voriconazole as part of the initial antifungal therapy was more common among survivors.

A TRANSNET study focused on only the 875 HSCT recipients found IA was the most common (43%) of all invasive fungal infections, followed by invasive candidiasis (28%).¹¹⁸ The median time of developing IA after HSCT was 99 days. Of the 80 cases of IA in autologous HSCT, 50% occurred within 1 month after receipt of transplant, whereas among allogeneic HSCT recipients, only 22% of cases occurred within 1 month after transplantation. Autologous HSCT recipients had an all-cause mortality rate of 13% at 12 months, and allogeneic recipients had a rate of 36% at 12 months after transplantation. The 12-month cumulative incidence for IA for all HSCT recipients was 1.6%, compared with 1.1% for invasive candidiasis, and the overall 1-year survival rate for HSCT recipients with IA was only 25.4%.

Another large database, the Prospective Antifungal Therapy (PATH) Alliance, also found IA was most common among HSCT recipients, and approximately 70% of the HSCT recipients with IA had undergone allogeneic transplantation. The median time for development of IA after HSCT was similar (82 days), with a diagnosis at a median of 51 days after autologous transplantation and 83 days after allogeneic transplantation.¹⁶⁴ Another study of HSCT recipients found the prognostic factors at diagnosis that strongly correlated with death due to IA were dissemination of IA, pleural effusion, low monocyte count, corticosteroids within the previous 2 months and receipt of a dose of 2 mg/kg or more at the time of diagnosis, and uncontrolled GVHD.⁴³

The TRANSNET database also analyzed all invasive fungal infections among SOT recipients and found that IA (19%) in this population was the second most common invasive fungal infection (unlike HSCT recipients) and invasive candidiasis (53%) was more common in SOT recipients.¹⁷⁵ The median time to onset of IA was 184 days after SOT transplantation, with a 1-year incidence of developing IA of 0.65% and a 12-month survival rate of 59%. The PATH Alliance analysis of SOT found that the likelihood of developing IA (25%) was second to that of invasive candidiasis but that IA was more common among lung transplant recipients (60%).¹⁶³ IA developed a median of 400 days after transplantation (including a median of 100 days after liver transplantation, 504 days after lung transplantation, and 384 days after heart transplantation). Most cases of IA among liver transplant recipients occurred less than 6 months after transplantation, whereas 62% of lung transplant recipients with IA developed the disease longer than 1 year after transplantation.

These findings contrasted with some of the results of a retrospective review of 158 cases of IA in Spanish SOT recipients, which found that 57% had early-onset IA (within 3 months after transplantation), but the mean time to development of IA was still 234 days.⁷⁹ The overall incidence of IA among their SOT recipients was 1.4%, with a similar distribution among specific organ transplant recipients, including an incidence of 3% for lung, 2.4% for heart, 2% for liver, and 0.2% for kidney transplantation. The overall mortality rate was 77%, with no significant differences found between SOT groups. Risk factors for developing early-onset IA included a complicated postoperative period, repeated bacterial infections or CMV disease, and renal failure.

One study found that 59% of patients with IA had neutropenia as risk factor, most of whom had hematologic or solid malignancies. Among the 41% of nonneutropenic patients, most had steroid-treated COPD, asthma, or rheumatologic disorders. Compared with neutropenic patients, the nonneutropenic patients were significantly less likely to have symptoms of IA and more likely to have frequent episodes of intercurrent pneumonia with another microorganism. The mortality rate was significantly higher among nonneutropenic (89%) compared with neutropenic patients (60%) with IA,⁴⁷ but the sensitivity of GM antigenemia was similar (approximately 65%) for neutropenic and nonneutropenic patients.

The risk of IA is expected to increase from 1% per day after the first 3 weeks of neutropenia to between 4% and 5% per day after 5 weeks,²⁰¹ with a 70% incidence after neutropenia exceeds 34 days.⁸¹ Prolonged or marked macrophage dysfunctions that occur as a result of underlying disease and its treatment can also predispose patients to IA. Risk of infection is higher with advanced underlying disease, transplantation during relapse of malignancy or chemotherapeutic rescue therapy, GVHD, or concurrent infection such as CMV.²⁰¹ In a survey of 24 medical centers and 148 IA patients, 30% also had a bacterial infection, 20% had a viral infection, and 19% had another fungal infection.¹⁸²

Corticosteroids are a major risk factor for the development of IA. They can suppress the ability of monocytes and macrophages to kill conidia through inhibition of nonoxidative processes and impairment of lysosomal activity. Corticosteroids also inhibit polymorphonuclear neutrophils in chemotaxis, oxidative bursts, and activity against hyphae.⁶⁸ Corticosteroids suppress macrophages, and cytotoxic chemotherapy decreases neutrophil number and function. Corticosteroids also greatly accelerate the growth of *A. fumigatus*, in one study decreasing the doubling time to 48 minutes.¹⁶⁵

In several studies of HSCT patient risk factors, only moderate to severe GVHD and steroid prophylaxis for GVHD^{21,147,191,257} or total-body irradiation²⁵⁷ were significant variables in the multivariate analyses. In one study, the parameters found to influence survival in the period from HSCT to diagnosis of fungal infection were related to the cumulative dose of prednisolone. In the multivariate analysis, there was a relative risk (RR) of 8.78 of death from IA for patients with acute, active GVHD (i.e., grade 2 or higher) or extensive, chronic GVHD combined with a cumulative total prednisolone dose of more than 7 mg/kg in the 1 week before diagnosis.¹⁹¹

There is little specific information on the fundamental epidemiology of pediatric IA, and most epidemiologic investigations do not offer pediatric analyses.^{46,76,120,257} One study found that the highest incidence

of IA was seen among children who had undergone allogeneic HSCT (4.5%) and those with acute myelogenous leukemia (AML) (4%). The incidence of IA among patients with AML was significantly greater than the incidence among patients with acute lymphoblastic leukemia (ALL) (RR, 5.6; 95% confidence interval [CI], 4.6–7.0).²⁵⁸

The largest detailed analysis was a retrospective multicenter study of 139 children with IA. *A. fumigatus* was the species most frequently recovered (52.8%), and most children had a malignancy with or without HSCT. Significant risk factors that affected survival were immunosuppressive therapies and allogeneic HSCT.³² Analysis of a large US pediatric inpatient database found an annual incidence of 0.4% of IA among immunocompromised children, and most had an underlying malignancy.²⁵⁸ The incidence of IA was 4.5% among children who underwent allogeneic HSCT, 4% among patients with AML, and 0.3% for those who underwent autologous HSCT. Lung transplant recipients had the greatest incidence (5%) of IA among pediatric SOT recipients. Children with CGD had an incidence of 6.5%, and those with Wiskott-Aldrich syndrome ($n = 267$) had a staggering incidence of 30%. For pediatric patients with specific underlying diseases with or without IA revealed, the RR of death was increased for CNS tumors (RR, 21.6), ALL (RR, 14.9), and lymphoma (RR, 13.5), showcasing the overall good survival rates of those with common pediatric malignancies and the devastating effect of adding IA to reasonably curable underlying pediatric malignancies.

The largest international, prospective cohort study on invasive mold infections in children (2007–11)²⁴⁹ included a total of 131 children and 98 (75%) with IA. Children with IA and those with other types of invasive mold infections had similar underlying risk factors, except that children with infections caused by non-*Aspergillus* species were more likely to have received mold-active antifungal agents preceding diagnosis. Among 43 patients who underwent HSCT, 27 (63%) underwent myeloablative conditioning. Of the 36 HSCT recipients who had complete information regarding timing of an invasive mold infection diagnosis from transplantation, five (14%) were diagnosed before or on the day of HSCT, and 31 (86%) were diagnosed at a median of 168 days after HSCT (interquartile range [IQR], 25–247). The distribution of the intervals from HSCT to invasive mold infection diagnosis was approximately bimodal, with 11 invasive mold infections diagnosed within the first 30 days and 2 diagnosed between 30 and 90 days.

DIAGNOSIS

The diagnosis of IA is often complicated. Due to myriad clinical manifestations, IA is categorized as proven, probable, or possible disease based on meeting certain clinical, microbiologic, and radiologic criteria designed and later revised by the European Organization for the Research and Treatment of Cancer and the Mycoses Study Group (EORTC/MSG).^{12,59} These criteria have served as a standard in clinical trials to segregate patients with similar disease characteristics, but the criteria are not perfect, and the designers have cautioned against their implementation in routine clinical practice. Nonetheless, these distinctions have served the community well by establishing a common framework for discussion about disease in high-risk patients. Proven and probable IA diagnoses can be considered as one entity because numerous clinical trials have shown their general equivalency in patient outcomes.

Cultures

A proven diagnosis of IA requires isolation from an otherwise sterile culture and histologic demonstration (Fig. 198.4).⁵⁹ No histopathologic finding can definitively diagnose the pathogen, and confirmation by culture or nonculture techniques is necessary to differentiate *Aspergillus* from other filamentous fungi such as *Fusarium* spp. and *Scedosporium* spp. Unfortunately, this gold standard of tissue biopsy is often considered too invasive and is complicated by bleeding or secondary infection in high-risk patients.

An important distinction for a positive *Aspergillus* culture must be made between disease and colonization. A 1-year retrospective study found that only 12% of patients with *Aspergillus*-positive cultures met the criteria for IA. A positive culture was associated with IA in 50% to 65% of high-risk patients, 8% to 28% of intermediate-risk patients, and almost no low-risk patients.¹⁸²

FIG. 198.4 Histopathologic findings of a lung biopsy show septate hyphae of invasive aspergillosis on Gomori methenamine silver stain. (Courtesy Thomas J Cummings, MD, Duke University Medical Center Pathology Department, Durham, NC.)

In one study, the predictive value of respiratory tract cultures from patients with IPA was 40% to 100%.²²⁵ Even in patients with established disease the sputum specimens are commonly negative,^{98,194} which is likely because IPA is predominantly infiltrative and does not have aerial growth in the bronchial tree.⁹⁸ Colonization with *Aspergillus* species has been a marker for reduced short-term survival because 12% of colonized patients died within 3 months of diagnosis. IPA was diagnosed in 12% of patients with a positive culture, but this figure is likely an underestimate because diagnosis was often made by radiographic imaging and culture specimens were not always obtained.¹⁸²

During a 10-year period in one study, *Aspergillus* species were recovered during 30 episodes from 27 heart transplant recipients (incidence of 10.5%). The overall positive predictive value was 60% to 70%, but it increased to 88% to 100% when the organism was recovered from a respiratory specimen other than sputum and decreased to 50% to 67% when it was recovered from sputum. The sensitivities of fungal and conventional media for the recovery of *Aspergillus* species were 95% to 100% and 33% to 38%, respectively.¹⁶⁰

Prior nasal colonization before transplantation has been a predictor of subsequent IPA in some studies,³ but it has not been duplicated in others.¹⁰⁸ Prior IA does not eliminate the chance of a successful HSCT. In one study, there were recurrences in nine patients with IA before transplantation, and all patients showed no signs of delayed engraftment compared with transplant recipients without a history of IA.²⁰³

IA is rarely diagnosed by blood culture.⁸³ In a study of 1477 separate positive cultures, there were more than a dozen positive blood cultures, but most were associated with pseudofungemia or terminal events observed at autopsy.¹⁸² The *Aspergillus* hyphal mass that develops in the lumen during angioinvasion typically remains in place until the force of blood flow causes hyphal breakage, which allows the mass to circulate. The likelihood of a blood culture capturing these irregularly and infrequently discharged units is small.

The difficulty in detecting *A. fumigatus* in blood culture contrasts with other angioinvasive filamentous fungi (e.g., *Fusarium* spp., *Paecilomyces lilacinus*, *Scedosporium prolificans*, *Acremonium* spp.), which have the ability to discharge a steady series of unicellular spores into the bloodstream and are more likely to be captured in a blood sample. This ability to sporulate in tissue and blood is called *adventitious sporulation*.²⁰⁰ Because *A. terreus* also displays adventitious sporulation, histopathology and KOH examination of these spores can allow rapid, presumptive identification of *A. terreus*. A blood culture positive for *A. terreus* or another mold that demonstrates adventitious sporulation should not be ignored, and a blood culture positive for other *Aspergillus* species should be further evaluated.

FIG. 198.5 In a 15-year-old adolescent with Schwachman-Diamond syndrome and acute myelogenous leukemia, computed tomography shows right lower lobe pulmonary nodules and a pleural effusion.

Radiology

IPA characteristically manifests on radiographs as multiple, ill-defined, 1- to 3-cm peripheral nodules that gradually coalesce into larger masses or areas of subsegmental and segmental consolidation. Lobar or diffuse pulmonary consolidation is a common finding.⁴¹ Chest radiographs can be abnormal, but in one series, they were normal for approximately 30% of patients in the week preceding death.¹⁹⁰

There are two classic radiologic signs of IPA. The halo sign is observed in neutropenic patients with a hemorrhagic nodule due to angioinvasion. An early CT finding of the halo sign is a rim of ground-glass opacity surrounding the nodule. In one study, the halo sign was seen in all patients with biopsy-proven IPA, but it is so nonspecific that it was also seen in patients with mucormycosis, organizing pneumonia, or pulmonary hemorrhage.²⁵⁶

Early lesions change into a cavitory lesion or lesion with an air crescent sign 2 to 3 weeks later, when neutropenia recovers.^{41,121} In one study, this was seen in 48% of patients 3 to 10 days after recovery of neutropenia.¹⁹⁷ Cavitation of the nodules or masses occurs in about 40% of patients and is characterized by an intracavitary mass composed of sloughed lung and a surrounding rim of air. A retrospective review of the CT finding for 47 autopsy-proven cases of IPA showed that nodular lesions and cavitation occurred significantly more often compared with controls.⁹¹

Just as the clinical presentation is nonspecific and heterogeneous, so are the findings in radiologic studies (Figs. 198.5 and 198.6). In most patients, disease is seen as round infiltrates, peripheral wedge-shaped lesions, and the typical halo sign early in the course of IPA during the neutropenic period, but in patients with CGD, hyphal angioinvasion is not a feature of disease, and the halo sign, cavitated lesions, and pulmonary infarcts therefore are not observed (Fig. 198.7). Instead, there are areas of tissue destruction due to acute and granulomatous inflammatory processes.¹⁵⁶

Long-term CT follow-up of 40 immunocompromised patients with IPA showed that formation of cavitation most strongly predicted the time until radiologic remission and beneficial outcome. The natural history of early IPA lesions was evaluated, and it was found that 90% of patients had an increase in lesion size and number, followed by a plateau in size and a decrease in number. Lesion cavitation developed in 55% of patients, and complete radiologic remission within a median of 80 days was observed in 42.5% of patients. The number of days until remission without cavitation (50 days) was less than for those with cavitation (95 days), and no cavitation strongly predicted radiologic remission.³⁰

In another study, the appearance of the air crescent sign had no relation to duration of neutropenia, and the sign had a tendency to

FIG. 198.6 In an 11-year-old child with cystic fibrosis after bilateral lung transplantation, computed tomography shows bibasilar nodular opacities. Encircled is a 1-cm opacity associated with some peripheral speculation.

FIG. 198.7 In a 9-year-old child with chronic granulomatous disease, computed tomography shows a soft tissue mass (arrow) in the anterior mediastinum with heterogenous enhancement. The mass caused a convex deformity of the left anterior chest wall.

appear in large lesions such as consolidations or masses rather than small lesions such as nodules.¹¹⁵ Repeat CT within 2 weeks of the start of treatment is not recommended unless the patient experiences clinical deterioration.¹⁷⁹ An exception is the finding of a nodule close to a large vessel because of the risk for massive hemoptysis if the lesion continues to increase in size. Routine use of contrast with CT is not recommended.

Adult and pediatric patients can have radiologic differences in IA. In adult series of IPA, approximately 50% of cases showed cavitation, and 40% had air crescent formation.⁸⁰ In one 10-year review of pediatric patients (mean age, 5 years), there was central cavitation of small nodules in only 25% and no evidence of air crescent formation in any area of consolidation.²²³ In another pediatric report, a 22% rate (six of 27 patients) of cavitation was determined by chest radiography,⁸ and in another, a 43% rate (six of 14 patients) of cavitation was demonstrated by CT.²²⁰ In the latter two pediatric series, the mean ages were higher than the first report of lower rates of cavitation and no air crescent formation, suggesting that there is a spectrum of radiologic disease that is directly related to age, with cavitation and air crescent formation more likely to occur in older children and adults than in younger children.

A review of 27 pediatric patients showed that radiographic changes developed after HSCT but before the diagnosis of pulmonary fungal

FIG. 198.8 A 3-year-old child with medulloblastoma who underwent chemotherapy and radiation therapy had new-onset acute mental status changes. T1-weighted axial magnetic resonance imaging showed multiple lesions in the subcortical area.

infection; it included unilateral infiltrates (52%) slightly more often than bilateral infiltrates. At the onset, the infiltrates were interstitial (41%), alveolar (41%), and mixed (18%). Hilar or mediastinal plural effusion or thickening and lymphadenopathy were rare. By the time of diagnosis of pulmonary fungal infection, the infiltrates were largely bilateral (66%) and alveolar or nodular (74%), and 22% of patients had cavitory lesions.⁸ The largest series of contemporary pediatric IA cases found the most common clinical site of IA was the lungs (59%), and the most frequent diagnostic radiologic finding was nodules (34.6%).³² Radiologic evaluation found the air crescent sign in only 2.2% of the children, the halo sign in 11%, and cavitation in 24.5%.³²

Thoracic MRI findings are not as specific as chest CT findings. The typical MRI finding is the target sign, a nodular lesion with lower signal intensity in the center compared with a higher, contrast-enhancing signal intensity in the rim on T1-weighted images. This sign suggests late-stage disease.²⁵ MRI is the modality of choice for diagnosing cerebral aspergillosis because its sensitivity is better than that of CT (Fig. 198.8). Images often demonstrate multiple lesions located in the basal ganglia that show an intermediate signal intensity, lack of contrast enhancement, and absence of a mass effect.¹⁵⁴ CT of the head often reveals one or more hypodense, well-demarcated lesions. Findings of hemorrhage and mass effect are unusual, but for patients with adequate peripheral white blood cell counts, a ring enhancement and surrounding edema are more common.⁴⁹ T2-weighted MRI shows very decreased signal intensity compared with images of bacterial sinusitis, which show increased signal intensity.⁴⁹

Serology

The *Aspergillus* IgG antibody test is the most sensitive microbiologic test for chronic pulmonary aspergillosis or ABPA in immunocompetent individuals, but unfortunately, serology plays little role in diagnosing the immunocompromised patient because *Aspergillus* growth does not correlate with an increase in anti-*Aspergillus* antibody titers.¹²⁸ For example, serologic examination of 18 patients with IA showed anti-*Aspergillus* antibody detection was negative in all cases, likely due to profound immunosuppression.¹⁹⁷

Despite the historical lack of success with antibody testing, there is a movement to consider using antibody testing for patients before immunosuppression in an attempt to discern who is most likely to later develop IA. In a study to evaluate antibody responses using an enzyme-linked immunosorbent assay (ELISA) format for different types of aspergillosis, results showed that three recombinant antigens had diagnostic potential.¹⁹⁶ The candidate recombinant antigens are 18-kd ribonuclease (RNU), 360-kd catalase, and 88-kd dipeptidylpeptidase V (DPPV). For aspergilloma patients, all three of the antigens were equally useful for diagnosis, but only catalase was useful for immunocompetent and immunocompromised patients.

Galactomannan Antigen

GM is a major cell wall component of *Aspergillus*, and the highest concentrations of GM are released in the terminal phases of the disease.¹²⁸ An ELISA technique was developed using a rat anti-GM monoclonal antibody (EB-A2) that recognizes the 1→5-β-D-galactofuranoside side chains of the GM molecule.¹³⁸ A sandwich ELISA technique was introduced in 1995,²¹⁵ and by using the same antibody as a capture and detector antibody in the sandwich ELISA (Platelia *Aspergillus*, Bio-Rad, Marnes-La-Coquette, France), the threshold for detection can be lowered to 1 ng/mL. This technique is employed in the commercially available GM assay for the diagnosis of IA.

In a meta-analysis conducted to characterize the clinical utility of the serum GM assay, 27 studies were identified, and overall, the GM assay had a sensitivity of 71% and a specificity of 89% for proven cases of IA as defined by the specific clinical criteria.¹⁸⁴ There was considerable heterogeneity among the studies, and in subgroup analysis, performance of the test varied by patient population and by which reference diagnostic standard was used. The assay was most useful for patients with hematologic malignancy or those who had undergone hematopoietic transplantation, but for solid organ transplant recipients, the sensitivity and specificity were 22% and 84%, respectively.

The latest guidelines¹⁷⁹ recommend serum and bronchoalveolar lavage (BAL) specimens for detection of GM, which is an accurate marker for the diagnosis of IA in adult and pediatric patients when used in certain patient subpopulations (e.g., hematologic malignancy, HSCT). GM testing is not recommended for routine blood screening of patients receiving mold-active antifungal therapy or prophylaxis, but it can be applied to bronchoscopy specimens from those patients. For patients receiving mold-active antifungal prophylaxis, the use of serum GM levels as a screening tool has a very poor predictive value, with most positive test results being false positives in this setting.⁶⁷ GM testing is not recommended for screening of solid organ transplant recipients or patients with CGD due to the low predictive value and high false-negative rates, respectively.

When used, serial testing twice weekly during periods of greatest risk is recommended.⁵² In one study, an increase in GM values during the first week of observation predicted treatment failure in allogeneic HSCT patients.²⁸ In a large, prospective study of hematology and HSCT patients with confirmed or probable IA, elevated GM values were detected in 65% of patients an average of 8.4 days before positive CT scans or cultures, and increased GM levels were detected in 40% of patients before the onset of clinical symptoms by a mean of 6.9 days. The test was performed easily, and results were available in 4 hours; two successive samples with elevated GM values were required for positivity.²¹⁶

The GM assay has decreased sensitivity in the setting of treatment with anti-*Aspergillus* (mold-active) antifungals, but the specificity for detection does not change.¹⁴⁰ Reduced sensitivity results from the decreased fungal burden in patients receiving mold-active antifungals. Unfortunately, those are exactly the high-risk patients for whom the GM assay would be used. A subsequent study found that the GM test was best performed for patients not receiving antifungals, for whom the sensitivity was 89%, compared with 52% for patients who received empiric mold-active antifungals.¹⁴⁴

Neutropenia also affects a GM-based diagnosis. GM values for patients with an absolute neutrophil count (ANC) less than 100 cells/μL and not receiving antifungal therapy were statistically higher than those for patients with an ANC greater than 100 cells/μL. However, GM values

were not statistically different for patients with an ANC less than 100 cells/μL and receiving antifungal therapy compared with those with an ANC greater than 100 cells/μL.⁴² This effect may result from a fungal burden that is higher at the time of initial IA in patients with neutropenia, or IA lesions may be more extensive in the setting of neutropenia.

The specific patient population tested is essential for optimizing GM testing usefulness.¹⁷⁹ Although GM has been extensively validated in patients with hematologic malignancy and those who have undergone HSCT, for unclear reasons, GM appears to be less useful for SOT recipients. When used for liver transplant recipients, there was a high false-positive rate, especially for patients with autoimmune liver disease or undergoing dialysis,¹²³ and in lung transplant recipients, sensitivity was greatly decreased, perhaps due to the pathophysiologic differences in *Aspergillus* tracheobronchitis and anastomotic disease seen in these patients.¹⁰² The serum GM level was not sensitive (38%) for patients with aspergilloma, but it improved for those with hemoptysis.¹⁷⁶ It is also not sensitive (23%) for patients with chronic pulmonary aspergillosis²⁰⁴ or COPD.¹⁰ GM testing of patients with CF who were colonized with *Aspergillus* species was consistently negative.²⁴⁷

The GM assay result has been repeatedly negative for patients with CGD and IA,^{155,235} potentially due to a lack of angioinvasion or immune complex formation with high levels of *Aspergillus* antibodies. One report described a nonneutropenic, 4-year old child with CGD and IA diagnosed by lung biopsy who had persistent false-negative serum GM testing.²³⁴ Similarly, serum GM values have been higher for patients with angioinvasive IA than those with IA that did not invade the airway.⁹⁷

False-positive results for GM testing can hamper its clinical utility and are seen for patients concurrently receiving some β-lactam antibacterials. Piperacillin-tazobactam was once the major cause of this false-positive reaction due to contamination with GM during the production process, but current formulations used in the United States are a rare cause of false-positive results.²³¹ One study that evaluated false-positive GM kinetics found a gradual increase in GM levels in patients receiving β-lactam antibacterials and an average of 5.5 days to a negative antigen test result.¹³ Several years ago, there were concerns about increased false-positive results for children, and one theory suggested it was caused by *Bifidobacterium bifidum* spp. in the gut microflora that mimic the epitope recognized by the EB-A2 probe in the ELISA kit¹⁵² and by GM-positive infant formula used by pediatric patients.¹ False-positive results probably are caused by the ELISA antibodies cross-reacting with specific antigens, many of which have not been defined, and this phenomenon is not associated with the patient's age.

Diagnosis of pediatric IA with GM, although originally reported to be less useful due to a higher false-positive rate,^{95,218} has been validated as effective for children.^{17,36,39,61,74,92,109,207} A study of 64 pediatric allogeneic HSCT recipients found that after excluding patients receiving piperacillin-tazobactam (previously known to cross-react because of GM contamination), the false-positive rate was only 1.6%, producing a specificity of 98.4% for this high-risk population. In that study, the GM test result was falsely positive for the first sample obtained after initiation of piperacillin-tazobactam, but cessation of piperacillin-tazobactam produced a negative test result in the subsequent samples obtained over 3 to 4 days.²⁰⁷ Another report of 56 pediatric oncology patients found a sensitivity of 66% with a specificity of 87%, and in six of seven cases of IA, the GM test result was positive before clinical or radiographic evidence of disease.⁹² A retrospective study found a similarly low false-positive rate (1.5%), and found that GM testing performed better in periods after aggressive chemotherapy than in those after allogeneic HSCT.³⁶

Bronchoalveolar Lavage

Guidelines state that bronchoscopy with BAL is recommended for patients with a suspicion of IPA.¹⁷⁹ Because the yield of BAL is low for peripheral nodular lesions, percutaneous or endobronchial lung biopsy should be considered. BAL should include routine culture, cytologic analysis, and non-culture-based methods (e.g., GM levels).

BAL is often useful in diagnosing IA, but a negative BAL culture does not conclusively rule out disease. A thorough review of the diagnostic yield of BAL specimens for histologically proven IA patients found

sensitivities of approximately 40% (range, 0–67%),¹⁸⁹ but in one study, BAL had a sensitivity of only 50%, even for patients with focal IA.¹⁴⁹ The sensitivity of respiratory tract culture specimens has been 15% to 69%,¹⁸² and in one study, it increased to 50% to 70% for high-risk IA groups.

The sensitivity of BAL samples may be increased by the use of GM testing, amplifying the yield of bronchoscopy and possibly avoiding the need for further invasive procedures. Although the GM cutoff value in serum samples is 0.5, the cutoff is best set at 1.0 for BAL GM testing. A retrospective analysis of 99 high-risk hematology patients, including 58 with IA, who underwent BAL for the diagnosis of new pulmonary infiltrates found that a BAL GM value of 1.0 or more yielded an increased sensitivity (91.3%) compared with BAL culture (50%) or BAL microscopy (53.3%). The combined sensitivity of all three BAL methods was 98.2%.¹³⁴ Further analyses in that study found that the mean BAL GM value was not different for neutropenic and nonneutropenic patients.

A meta-analysis of BAL GM studies found sensitivities between 59% and 100% and specificities between 76% and 100%. Antifungal therapy did not significantly affect sensitivity, as it does with serum GM assays.⁸⁸ A retrospective study of patients with hematologic malignancies and HSCT recipients also found that BAL GM testing was more sensitive than serum GM assays for diagnosing IA and determined that BAL GM results were not affected by mold-active antifungals, suggesting that these findings might reflect the different levels of antifungals found in sera and alveolar fluid. This study supported the use of BAL GM testing to diagnose IA because the positive predictive value was optimized, whereas serum GM testing might be best applied as a screening test with the use of a lower cutoff value to maximize the negative predictive value.¹⁶⁶ A retrospective study of pediatric BAL GM testing found an optimal BAL GM cutoff of 0.98 to yield the best sensitivity (78%) and specificity (92%). Using a BAL GM value of 1.0 or higher and a concurrent serum GM value of 0.5 or higher yielded the best sensitivity (89%) and specificity (90%).⁶⁰

(1→3)-β-D-Glucan

(1→3)-β-D-Glucan is an integral cell wall component, and in contrast to GM, it is not normally released from the fungal cell.¹²⁸ Factor G, a coagulation factor of the horseshoe crab, is a highly sensitive natural detector of (1→3)-β-D-glucan.¹⁶⁸ The G test detects the fungal cell wall component (1→3)-β-D-glucan with a modified limulus endotoxin assay, but it does not identify the genus of the fungi detected.¹⁶⁸ Unlike the GM assay, this assay is nonspecific and detects several fungi, including *Aspergillus* spp., *Candida* spp., *Fusarium* spp., *Trichosporon* spp., *Saccharomyces cerevisiae*, *Acremonium*, *Coccidioides immitis*, *Histoplasma capsulatum*, *Sporothrix schenckii*, and *Pneumocystis jiroveci*. The (1→3)-β-D-glucan assay does not detect *Cryptococcus* and the yeast form of *Blastomyces dermatitidis*, which produce low levels of (1→3)-β-D-glucan, or *Absidia*, *Mucor*, and *Rhizopus*, which produce no (1→3)-β-D-glucan.

False-positive results can occur in a variety of contexts, such as through glucan-contaminated blood collection tubes, gauze, depth-type membrane filters for blood processing, and various drugs such as antibiotics, including some cephalosporins, carbapenems, and ampicillin-sulbactam, and possibly chemotherapeutics such as PEG asparaginase.¹⁴⁸ The Fungitell assay (Associates of Cape Cod) for detection of (1→3)-β-D-glucan is cleared by the US Food and Drug Administration (FDA) for the diagnosis of invasive mycoses, including aspergillosis, and it has been evaluated in high-risk patients with hematologic malignancies and allogeneic HSCT recipients.^{169,172} A 1-year prospective study of patients with hematologic malignancies and controls found the sensitivities were 79% for real-time PCR, 58% for the GM assay, and 67% for the G test; specificities were 92%, 97%, and 84%, respectively.¹¹¹

In one study comparing (1→3)-β-D-glucan and GM assays, the sensitivity, specificity, and positive and negative predictive values were identical. False-positive reactions occurred at a rate of 10.3% in both tests, but the patients with false-positive results were different in each test. Both tests anticipated the clinical diagnosis and CT abnormalities, but the (1→3)-β-D-glucan assay result tended to become positive earlier than for GM testing. A combination of the two tests improved the

specificity to 100% and positive predictive value to 100% for each test without affecting the sensitivity and negative predictive values.¹⁸⁰ Another study compared GM, PCR, and (1→3)-β-D-glucan assays for patients with hematologic disorders, and the receiver operating characteristic (ROC) analysis showed that the area under the ROC curve was greatest for the GM assay using two consecutive positive results. This suggests that the GM assay was the most sensitive in predicting the diagnosis of IA for high-risk patients with hematologic disorders.¹¹⁴ A meta-analysis of cohort studies of the (1→3)-β-D-glucan assay for IA revealed that using a single test resulted in a pooled sensitivity of 57% with a specificity of 97%.¹²⁴

Comparative studies have shown that the Fungitell assay can be slightly more sensitive than GM testing for IA, but it is limited by its poor specificity,²¹⁷ whereas others have found that the Fungitell assay is not as helpful for diagnosing IA.¹⁷ However, another study in a large cancer center that compared GM and (1→3)-β-D-glucan assays prospectively over a 3-year period for 82 patients (each for 12 weeks) found that the (1→3)-β-D-glucan assay was more sensitive than the GM assays for detection of IA and other mold infections in patients with hematologic malignancies.⁹⁰ One meta-analysis of β-glucan assays revealed limitations,¹²⁴ whereas another found similar deficiencies but improvement in diagnostic capabilities with the combination of both biomarkers.¹⁸⁰ The 2016 guidelines recommend serum assays for (1→3)-β-D-glucan for diagnosing IA in high-risk patients (e.g., hematologic malignancies, allogeneic HSCT), but they are not specific for *Aspergillus*.¹⁷⁹ Other organizations have recommended the GM over Fungitell assay for specifically diagnosing IA.¹³⁹

Polymerase Chain Reaction

The exact clinical utility of blood-based PCR in diagnosing IA is unclear. The 2016 guidelines state that direct comparison studies have shown *Aspergillus* PCR to be substantially more sensitive than culture of blood and respiratory fluids.¹⁷⁹ In a meta-analysis of clinical trials evaluating the accuracy of serum or whole-blood PCR assays for IA, sensitivity and specificity were 84% and 76%, respectively.¹¹ These values are promising, but PCR of blood or serum alone is unable to confirm or exclude suspected IA in high-risk patients. The sensitivity of *Aspergillus* PCR for BAL fluid was higher than for blood samples, but in many instances, its specificity was lower.^{14,93}

In a systematic review of nine cohort studies using reference IA definitions that strictly adhered to the 2002 or 2008 EORTC/MSG criteria, the summary sensitivity and specificity values for the diagnosis of proven or probable IPA by PCR of BAL fluid were 77.2% and 93.5%, respectively.¹⁴ One difficulty is that the lungs are often colonized by *Aspergillus* (particularly in many high-risk populations, such as lung transplant recipients) and that PCR cannot differentiate colonization from disease or distinguish different *Aspergillus* spp. The high negative predictive value of BAL PCR (usually ≥95%) suggests a role in ruling out IPA. The data suggest that the diagnostic performance of blood or BAL PCR is comparable to that of serum and BAL GM index and that sensitivity for both tests is affected by antifungal use. Using both PCR and GM detection in serum improved sensitivity with no sacrifice of specificity.¹⁴

Despite promising results, *Aspergillus* PCR cannot be recommended for routine use in clinical practice because few assays have been standardized and validated, and the role of PCR testing in patient management is not established. Initiatives such as the European *Aspergillus* PCR Initiative (EAPCRI) have made significant progress in developing a consensus standard protocol for blood-based *Aspergillus* PCR.²⁵² This diagnostic method is not commercially available, and reports can be difficult to interpret due to the lack of experimental standardization between centers. Due to the ubiquitous nature of the mold, the value of this test will likely be its high negative predictive value.

TREATMENT

Overall success in treating IA depends on more than the choice of a specific antifungal. Detailed knowledge of host factors, underlying disease, concomitant infections, and degree and duration of immunosuppression are key to the overall management of IA in immunocompromised

patients. Immune reconstitution is paramount for successful IA therapy, and continued exposure to certain immunosuppressive medications, such as corticosteroids, worsens IA. Antifungal prophylaxis used before the diagnosis of IA can affect the ultimate choice of empiric or targeted therapy. The diagnostic workup should be aggressive to confirm disease, but it should never delay antifungal therapy if IA is a concern.

The cornerstone of antifungal therapy for IA is prompt and aggressive institution of antifungal therapy based on diagnostic results and on clinical suspicion of infection if the diagnosis is not immediately made. Antifungal resistance is slowly increasing among *Aspergillus* isolates, and it continues to have specific geographic trends that influence antifungal choice, although for the moment, it seems to spare much of the United States. There also are questions about whether to use antifungal monotherapy or combination antifungal therapy and which classes of agents should be used.

Although immune reconstitution is paramount, the role and real benefit of adjunctive immunotherapy remains unclear. Treatment for most forms of IA follows the 2016 recommendations made for the more common IPA.¹⁷⁹ Most of the treatment section focuses on IPA, with additional comments provided on the more common chronic and allergic forms of IA.

Treatment for Invasive Aspergillosis

Primary Antifungal Therapy

The 2016 Infectious Diseases Society of America treatment guidelines¹⁷⁹ recommend primary (initial) treatment with voriconazole. These recommendations mirror guidelines from many other international groups, which recommend voriconazole for the primary treatment of IA^{4,26,135,158,179,240} in all clinical sites. Alternative therapies include liposomal amphotericin B, isavuconazole, and other lipid formulations of amphotericin B. Combination primary antifungal therapy with voriconazole plus an echinocandin may be considered, but it is not necessarily recommended in selected patients with documented IA. Primary therapy with an echinocandin is not recommended, but an echinocandin can be used in the settings in which azole or polyene antifungals are contraindicated. Treatment of children with IA uses the same recommended agents as for adult patients, but the dosing is often very different, and for some antifungals, the exact dosing in children is unknown.

Treatment of IA should be continued for a minimum of 6 to 12 weeks, depending on the degree and duration of immunosuppression, site of disease, and evidence of disease improvement. Patients treated successfully who require subsequent immunosuppression should receive secondary prophylaxis to prevent recurrence. Many experts think treatment should continue until complete clinical and radiographic resolution of disease, often with an accompanying significant decrease in biomarkers (e.g., GM). If a patient remains substantially chronically immunosuppressed due to ongoing cytotoxic chemotherapy or lack of engraftment after HSCT, it is advisable to continue the antifungal therapy for IA until there is no evidence of disease, often 3 months or longer.

Surgical therapy may be useful for patients with lesions contiguous with the great vessels of the pericardium to avoid fatal hemoptysis. However, surgery to debulk disseminated lesions usually is not advised.

Since its approval for use in 1958, amphotericin B deoxycholate was the first-line therapy for IA and the gold standard against which other therapies were measured. However, with overall survival rates of about 35% among patients treated with amphotericin B for several decades and limited tolerance as a result of acute and chronic toxicities, there was a clear need to develop a better antifungal. Itraconazole became available in 1990 for the treatment of IA, but it was not without flaws, particularly decreased fungicidal activity compared with amphotericin B, unpredictable bioavailability of the capsular formulation in high-risk patients, and significant drug interactions.²¹¹

The next step taken in the search for a better antifungal was development of three lipid formulations of amphotericin B, whose advantages included an increased daily dose of the parent drug, high tissue concentrations with better delivery to reticuloendothelial organs, decreased infusion-related side effects, and decreased renal toxicity.⁶² These three lipid formulations—amphotericin B lipid complex, amphotericin B colloidal dispersion, and liposomal amphotericin B—provided

greater safety for patients who could not tolerate conventional amphotericin B.²¹¹

Voriconazole is a second-generation triazole and a synthetic derivative of fluconazole that was approved for use in the United States in May 2002 for treatment of IA. The global clinical trial that led to its approval prospectively showed that voriconazole had a superior response rate in the primary treatment of IA compared with amphotericin B deoxycholate (52.8% vs. 31.6%). Survival rates increased from 57.9% for amphotericin B to 70.8% for voriconazole.⁹⁴ A secondary analysis of the study's results, which employed the most recent consensus definitions of invasive fungal disease that were unavailable at the time of the original trial,⁵⁹ revealed slightly more favorable results for voriconazole compared with amphotericin B.⁹⁶ Although the original 2002 study was criticized for employing conventional amphotericin B as the comparator to voriconazole (due to approval indications at the time of study design), later analysis clearly showed that primary therapy with voriconazole was superior to primary therapy with amphotericin B, regardless of subsequent switching for intolerance of refractory disease to any other licensed antifungal therapies (e.g. liposomal amphotericin B, itraconazole, other agents).¹⁷⁸

Later epidemiologic studies have confirmed the benefit of voriconazole compared with the decades of data on amphotericin B. Although controlled clinical trials have the benefit of rigorous evaluation, they often suffer certain biases because of enrollment of a generally healthier patient population. A Belgian multicenter observational study followed 113 adult patients with IA and found an overall successful response rate, typically viewed in antifungal clinical trials as the sum of the complete response rate and partial response rate, of 50.4% with voriconazole.¹⁰³ A French epidemiologic study found similar results by analyzing 393 adult patients with IA and concluded that any treatment regimen containing voriconazole, alone or in an antifungal combination, was superior in terms of survival to any antifungal regimen without voriconazole.¹³¹

The improved voriconazole response rate has translated well to the pediatric population, as shown by a review of 42 children treated for IA with voriconazole.²⁴⁴ An analysis of the compassionate open-label use of voriconazole in children for refractory IA demonstrated a 43% complete or partial response rate. Voriconazole was also shown in these studies to be better tolerated and to have less toxicity than amphotericin B in adults and children.

The fundamental pharmacokinetics of voriconazole are different in children (i.e., linear) than in adults (i.e., nonlinear).²⁴³ For instance, although the recommended starting dose of voriconazole for adult patients is 6 mg/kg twice daily for the first day and the maintenance dose is 4 mg/kg twice daily, the preferred pediatric dosage is substantially higher. Population pharmacokinetic analyses of voriconazole in children, adolescents, and adults, which are based on the area under the concentration-time curve, reveal that children should be given an intravenous 9 mg/kg loading dose to be comparable to the 6 mg/kg dose given to adults.⁷⁵ The maintenance intravenous dose for children of 8 mg/kg was comparable to the dose of 4 mg/kg for adults, and the oral pediatric dose of 9 mg/kg was found to be similar to that for adults receiving 200 mg of oral voriconazole twice daily.

Most adolescents can be dosed as adults, but for younger adolescents (12–14 years), the analysis found that body weight was more important than age in predicting voriconazole pharmacokinetics. During this age transition period, adolescents 12 to 14 years of age should be dosed as children if their weight is less than 50 kg and dosed as adults if their weight is 50 kg or higher.⁷⁵ The oral bioavailability of voriconazole, although thought to be greater than 95% in adults, is approximately 50% to 65% in children.^{112,242} This is important for patients receiving oral voriconazole long after transplantation and during the second bimodal peak of disease at approximately day 100 after transplantation. Higher voriconazole doses may be needed in some cases. A population pharmacokinetic analysis of adult patients found that higher voriconazole doses were required to achieve adequate therapeutic serum trough levels.¹⁷⁷

The triazole antifungals require therapeutic drug monitoring. Effective management of IA requires obtaining a voriconazole trough level, which has high interpatient variability that limits its extrapolation to a larger

population but much lower inpatient variability, allowing successive trough levels to be used to monitor dose adjustments for individual patients.²⁰⁶ The exact voriconazole trough level for clinical efficacy against IA is uncertain because in several clinical studies, some patients have had undetectable voriconazole levels but had clinical responses. However, a serum trough level that is greater than the usual minimal inhibitory concentration (MIC) of the infecting *Aspergillus* species is preferable. Although individual studies have debated the exact cutoff, it is clear that the serum level should be a true trough level and not a random drug level.

Most experts advocate for a serum trough voriconazole level of 2.0 µg/mL or higher and stress the importance tailoring therapy for each patient. Inherent in the individualized treatment approach is the understanding that various populations metabolize voriconazole differently. Three major genotypes due to allelic polymorphisms in the human cytochrome P450 isoenzymes (largely CYP2C19) are responsible for voriconazole metabolism.¹¹⁰

The choice of primary antifungal therapy must address concerns about azole-resistant, often panazole-resistant, isolates in specific geographic regions of the world. An international (largely European) surveillance study of approximately 4000 isolates from 19 countries found the azole resistance rate for *A. fumigatus* was 3.2%, and azole resistance was documented in 5.1% of IA cases.²²⁹ This is especially worrisome because approximately 70% of patients with azole-resistant IA have never received an azole antifungal. Of the many genotypes uncovered in azole-resistant species, TR₃₄/L98H and TR₄₆/Y121F/T289A are responsible for 80% of azole-resistant IA.²³² These genotypes denote mutations in the *cyp51A* gene, which encodes the target enzyme of the azoles, and a tandem repeat of 34 or 46 base pairs in the *cyp51A* promoter region.

Epidemiologic cutoff values have been established for determining likely clinical resistance for itraconazole (1 µg/mL), voriconazole (1 µg/mL), posaconazole (0.25 µg/mL), and preliminarily for isavuconazole (1 µg/mL).⁶⁹ An international expert opinion panel recommended azole susceptibilities for all *Aspergillus* isolates, and if an isolate is determined to be azole resistant, they advise switching to liposomal amphotericin B, using voriconazole plus echinocandin, or considering a non-azole-based regimen (e.g., echinocandin).²³² For empiric therapy, if the rate of environmental resistance is 10% or higher, voriconazole plus echinocandin or liposomal amphotericin B should be used initially.

Alternative Antifungal Therapy

An alternative for primary treatment of IA is liposomal amphotericin B. Although no randomized trial has been performed to evaluate effectiveness of this drug compared with voriconazole for primary therapy, a series of randomized trials suggest therapeutic effectiveness. Amphotericin B has always been considered a concentration-dependent antifungal, and one clinical trial compared liposomal amphotericin B at 3 mg/kg per day ($n = 107$ patients) and 10 mg/kg per day ($n = 94$ patients).⁴⁴ The favorable overall response for the lower dose (50%) and the higher dose (46%) were similar, with no demonstrable additional benefit for higher amphotericin B dosing and found higher rates of nephrotoxicity. Although these response rates are similar to the favorable response seen earlier with voriconazole,⁹⁴ most of the amphotericin B responses were partial responses and not complete treatment responses, suggesting that the triazole was overall more effective in disease eradication.

The results suggest that liposomal amphotericin B should be considered as alternative primary therapy for some patients, especially when hepatic toxicities or drug interactions warrant nonazole alternatives and when voriconazole-resistant molds (e.g., mucormycosis) remain a concern. Because conventional amphotericin B was shown to be inferior to voriconazole, few experts recommend conventional amphotericin B for IA management.

A pivotal randomized trial compared voriconazole with isavuconazole and demonstrated noninferiority in the treatment of IPA.¹³⁷ This multicenter, randomized, double-blind study of patients 18 years of age or older showed noninferiority (19% for isavuconazole vs. 20% for voriconazole) in terms of the primary end point of all-cause mortality at 6 weeks in the intent-to-treat population of patients with possible, probable, and proven aspergillosis. There were also fewer drug-related

adverse effects for people who received isavuconazole (42% vs. 60%). Based on these data, isavuconazole was approved by the FDA for first-line therapy of IA and is recommended as an alternative primary therapy for IA.

Salvage Antifungal Therapy

Salvage therapy is defined as treatment after primary therapy, often because of ineffectiveness or patient intolerance. Guidelines recommend an individualized approach that considers the rapidity, severity, and extent of infection; patient comorbidities; and the need to exclude the emergence of a new pathogen.¹⁷⁹ There should be an aggressive and prompt attempt to establish a specific, correct diagnosis, which includes bronchoscopy with or without CT-guided biopsy. For example, mucormycosis and aspergillosis appear radiographically similar, but treatment of mucormycosis with voriconazole is unsuccessful. Assuming that the diagnosis of IA is correct, the first step in treating refractory disease is to establish that the correct dose of voriconazole is being used. Documentation of serum azole levels should also be verified if therapeutic drug monitoring is available because this has historically been a common cause of antifungal failure.

The general strategies for salvage therapy typically include changing the class of antifungal, tapering or reversal of underlying immunosuppression when feasible, susceptibility testing of any *Aspergillus* isolates recovered from the patient, and surgical resection of necrotic lesions in selected cases. In the context of salvage therapy, an additional antifungal agent may be added to current therapy, or combination antifungal drugs from different classes other than those in the initial regimen may be used. For patients currently receiving an antifungal and exhibiting an adverse event attributable to the agent, it makes sense to change to an alternative class of antifungal or the use of an alternative agent with a nonoverlapping side effect profile. For salvage therapy, agents include lipid formulations of amphotericin B, micafungin, caspofungin, posaconazole, and itraconazole.

Choosing appropriate antifungal therapy is especially important in the setting of prior azole exposure (i.e., antifungal prophylaxis before diagnosis) because of concerns about development of antifungal resistance. Itraconazole resistance was first described in 1997,⁵⁸ and resistance to echinocandins largely results from researchers genetically modifying the *fkp1* gene (i.e., target of echinocandins) in *A. fumigatus*.¹⁹³ However, azole resistance is increasing among clinical strains,³¹ including multiazole- or panazole-resistant (e.g., voriconazole, posaconazole, itraconazole) strains. Azole resistance in *A. fumigatus* has emerged over the past decade, with a prevalence as high as 5% to 13% in the Netherlands and Great Britain.^{101,230} The most common multiazole-resistance mechanism consists of mutations in the *cyp51A* gene, which is involved in ergosterol biosynthesis.²³³

Some *Aspergillus* species are more likely to be resistant to certain antifungals. *A. terreus* is a recalcitrant *Aspergillus* species due to its in vitro resistance to amphotericin B,²¹⁹ which has been confirmed in animal models.²⁴⁵ A review of in vitro analyses, multiple animal models, and previously reported clinical cases showed almost uniform failure with amphotericin B against *A. terreus*.²¹⁰ A multicenter, retrospective analysis of more than 80 cases demonstrated that the mortality rate was decreased for patients who received voriconazole instead of amphotericin B therapy.²⁰⁸ Other studies have shown that patients with *A. terreus* disease are more likely to be neutropenic,⁸⁹ more likely to have disseminated disease, and have a decreased response to all classes of antifungals compared with patients infected with *A. fumigatus*.¹²⁶

Newer species, such as *Aspergillus lentulus*,¹⁸ *Aspergillus udagawae* (formerly *Neosartorya udagawae*),²³⁶ and *Aspergillus pseudofischeri*,¹⁰⁷ have been described, and many have reduced antifungal susceptibility.⁶ Two studies that analyzed the MIC distribution of more than 5000 isolates showed that some species are significantly more susceptible to amphotericin B, itraconazole, or voriconazole.^{70,71} In the case of *A. pseudofischeri* and *A. udagawae*, susceptibility to amphotericin B and itraconazole is somewhat controversial, but the general consensus is that these species are less susceptible to voriconazole than *A. fumigatus*.^{19,186} *Aspergillus calidoustus* is resistant to all azoles.^{5,16} *A. lentulus* is overall less susceptible than *A. fumigatus* to amphotericin B, itraconazole, and voriconazole based on its high MICs.¹⁹

There are no randomized studies examining posaconazole for primary therapy of IA, but numerous in vitro and in vivo data suggest that this triazole can be as effective as voriconazole as a potential first-line agent against IA. A multicenter study of salvage therapy evaluated 107 patients with IA treated with posaconazole compared with 86 historical controls and found response rates of 42% and 26%, respectively, and found improved survival rates at 30 days of 74% and 49%, respectively.²⁴⁶ This study was significant because all patients had salvage therapy (usually after failing amphotericin B products or itraconazole), demonstrating that the newer triazoles are the best treatment option for IA.

Additional studies support the argument for using triazoles. Voriconazole or posaconazole therapy was associated with fewer deaths compared with amphotericin B products or caspofungin in an Italian study of 140 patients with IA and AML.¹⁷³ Voriconazole therapy produced more survivors than caspofungin, amphotericin B formulations, or itraconazole among 642 patients with IA who were HSCT and SOT recipients in the United States.¹⁵

Three echinocandins are approved in the United States: caspofungin, micafungin, and anidulafungin. Several in vitro antifungal susceptibility studies have shown the general equivalency of all three echinocandins against *Aspergillus* species.¹⁸³ The echinocandin activity against *Aspergillus* is fungistatic compared with triazole fungicidal activity. Because it blunts the hyphal tip but does not kill the organism,²⁹ activity is reported as the in vitro minimal effective concentration (MEC), not the MIC.¹²²

Caspofungin was first studied in an open-label, noncomparative study of salvage therapy for immunocompromised patients with proven or probable aspergillosis.¹³⁶ Caspofungin produced a complete or partial response in 45% (37 of 83) of patients, which is significant because the patients were refractory to or intolerant of previous antifungal therapy. These findings were validated by two subsequent clinical trials in which caspofungin resulted in complete resolution or stabilization of disease in 74% patients ($n = 31$) in one, and in the other trial, caspofungin had an overall response rate of 56% ($n = 32$).^{35,226} Few studies have evaluated caspofungin as primary therapy for IA. One phase II dose-escalation clinical trial evaluated 46 patients with caspofungin as primary therapy and found a favorable response rate of 54.3% but found no dose-dependent effect on efficacy for caspofungin.⁴⁵ A later observational study of caspofungin as primary or salvage therapy and as monotherapy or in a combination approach found an overall 56.4% favorable response rate, validating caspofungin as a viable therapeutic option.¹³³

The largest study with micafungin was a noncomparative, open-label, multicenter study of adult and pediatric patients that examined the safety and efficacy of micafungin in the treatment patients with IA who had failed to respond to prior therapy or could not tolerate other therapies. Of the 225 patients who met diagnostic criteria, 35.6% (80 of 225) had a favorable response, and of those treated with only micafungin, a 50% (six of 12) of the primary therapy group and 40.9% (nine of 22) of the salvage therapy group had a favorable response.⁵⁴ Anidulafungin is approved in the United States for the treatment of candidemia and esophageal candidiasis. Although in vitro studies show activity against *Aspergillus* species isolates, there are no clinical studies of anidulafungin used against IA as primary or salvage monotherapy.

Combination Antifungal Therapy

Although no controlled clinical trial fully supports its efficacy for treating IA and use is not recommended by guidelines, clinicians who are desperately seeking new strategies to improve outcomes sometimes turn to combination antifungal therapy. With the surge in the development of newer antifungals for IA, more permutations of combination antifungal therapies are available. Drawing from treatments for other diseases such as human immunodeficiency virus (HIV) infection, tuberculosis, and cryptococcal meningitis (CM),²² combination therapy for IA seems a plausible approach to optimize therapy. Unfortunately, the range of data from in vitro experiments, animal model studies, and small clinical series extend from synergy to antagonism and parallel the wide range of unproven treatment practices used by clinicians who are searching for the best care for their patients.

The largest analysis of combination therapy for IA reviewed 6281 cases of IA management from 1966 through 2001, focusing on 249 clinical uses of combination therapy reported in 128 articles.²¹²

Unfortunately, three combination regimens that are not commonly used now nor currently recommended (i.e., amphotericin B plus flucytosine, amphotericin B plus itraconazole, and amphotericin B plus rifampin) comprised most of the reported clinical experience at that time. Although these data helped to lay the foundation for combination therapy in the past, the drug combinations used historically are not those necessarily applied by clinicians in current practice.

Combination antifungal therapy has several likely advantages: a widened spectrum and potency of drug activity, more rapid antifungal effect, drug synergy, lowered dosing of toxic drugs, and a reduced risk of antifungal resistance.¹²⁹ Although each antifungal agent has limitations, combination regimens may prove more effective, as demonstrated by the highly active antiretroviral therapy (HAART) used for treating HIV patients. Without large-scale clinical trials, clinicians often derive treatment strategy information from experimental in vitro or in vivo data. Unfortunately, due to the extensive heterogeneity of experimentation and interpretation, firm conclusions cannot be drawn about the clinical relevance of the combination antifungal experiments. In vitro combination drug testing is useful for screening antagonistic interactions before investigating further in animal model or clinical studies.

Animal model testing is preferred over in vitro analysis because of greater predictive value for human pharmacokinetic and pharmacodynamic effects, including tissue penetration and achievable drug levels at the foci of infection, and for determining toxicities. In vivo testing also can be used to compare various disease location models and analyze different host immune states. Histologic examination is used to determine fungal sterilization. Although in vitro testing can suggest an effective antifungal, the dose needed to achieve the desired effect may be unachievable safely in vivo, or the drug may not penetrate infected tissue adequately.

For combination antifungal therapy to be viable, the combination treatment needs to be superior to any of the individual therapies. Voriconazole has made this task more complicated because the agent is quite effective at killing *Aspergillus*, sterilizing infected tissue in numerous animal models, and clinically curing patients who were once thought to be hopeless. Regardless of the continuous stream of data, the in vitro and in vivo interactions must continue to be questioned due to so many confounding patient variables. Clinical experience remains the most accurate tool, but clinical relevance may be related to patient factors (e.g., recovery of neutropenia, cessation of glucocorticoid therapy) and not intrinsically related to the susceptibility of the fungus to voriconazole.

Combination in vitro testing has many potential pitfalls, and the final fractional inhibitory concentration index (FICI), the mathematical foundation behind the commonly used checkerboard test, can be clinically deceiving. For example, the interaction between fluconazole and terbinafine in one study was reported to be synergistic against *A. fumigatus* strains (FICI, 0.38).¹⁵⁷ However, individually fluconazole is known to have zero anti-*Aspergillus* activity, and terbinafine has poor tissue penetrance,⁹⁹ and the combination would appear to be a poor clinical choice for IA. The individual MIC of fluconazole was 512 µg/mL, and that terbinafine was 8 µg/mL, but both improved in combination to 64 µg/mL and 2 µg/mL, respectively, mathematically achieving the definition of antifungal synergy. However, it could be argued that this result indicates that two already poor choices for treatment were made less poor in combination. It is unlikely clinicians would advocate combination fluconazole plus terbinafine for their IA patients despite a final result of synergy based on in vitro testing.

In vitro drug combination studies have inherent experimental variations, and there is no standardization in animal model experimentation. If a single antifungal offers as much as 50% protection or many infected control animals survive, it can be difficult to show improvement with combination therapy over single agents.⁸⁵ Many variables influence the outcome of animal model experiments (similar to patient cases), including the degree of neutropenia, route of infection determining which target organs are infected, timing of drug delivery, tissue processing, and fungal burden measurement.

In the clinical setting, the antifungal combination of voriconazole plus caspofungin has the most anecdotal experience, likely because of approval and availability and the presumed synergistic interaction due

to the simultaneous inhibition of (1→3)- β -D-glucan synthesis in the fungal cell wall and ergosterol synthesis in the fungal cell membrane.^{116,181} One clinical study analyzed voriconazole plus caspofungin in a retrospective review of 47 patients with proven or probable IA from 1997 to 2001 who experienced failure of primary therapy with amphotericin B formulations.¹⁴¹ Salvage therapy was begun with voriconazole ($n = 31$) or with voriconazole plus caspofungin ($n = 16$) after 7 or more days of failed amphotericin B therapy. The overall survival rate 3 months after the day of diagnosis of IA was slightly higher among those who received combination therapy ($P = .048$). In the bivariate analysis (controlling for antifungal therapy and receipt of HSCT), the combination showed an improved 3-month overall survival rate (HR, 0.27; 95% CI, 0.09–0.78; $P = .008$). An accompanying editorial to the article pointed out that the preclinical data for combination therapy seemed promising but inconsistent.²³⁸ The authors responded,³⁷ and in analyzing the patients at 1 year, found there was no difference in overall survival ($P = .26$).

The prevailing expert opinion is that if a combination antifungal therapy approach is beneficial for treating IA, the combination should include a cell membrane–active triazole and a cell wall–active echinocandin. It is unclear whether any combination therapy can produce the great advance seen with the use of voriconazole instead of conventional amphotericin B due to the increasing fragility of immunosuppressed patients with IA. Although the latest treatment guidelines state that primary combination antifungal therapy is not routinely recommended based on a lack of definitive clinical data, one retrospective study used voriconazole plus caspofungin primary combination therapy for lung transplant recipients because of the known delay in time to achieve an adequate voriconazole serum level, thereby using the second agent only during the initial early weeks of therapy.²²²

In a large, double-blind, placebo-controlled, randomized trial of combination antifungal therapy, voriconazole monotherapy was compared with combination therapy using voriconazole plus anidulafungin for primary therapy of IA.¹⁴⁶ A total of 454 patients with hematologic malignancies who were 16 years of age or older were randomized in a 1:1 ratio in the study and given voriconazole alone or combination therapy for a minimum of 2 weeks, followed by voriconazole monotherapy to complete 6 weeks of treatment. The primary efficacy end point was the 6-week, all-cause mortality rate for the patients with confirmed proven or probable IA. The mortality rates at 6 weeks were 19.3% for combination therapy recipients and 27.5% for monotherapy recipients ($P = .087$; 95% CI, –19 to 1.5). Although the results for combination therapy demonstrated a substantial benefit, the difference did not achieve the prespecified threshold for statistical superiority. In post hoc analyses of the subgroup of patients who were diagnosed as having probable aspergillosis based on radiographic abnormalities and positive GM assays, the difference in mortality rates was most notable (15.7% for combination therapy vs. 27.3% for monotherapy; $P = 0.037$; 95% CI, –22.7 to –0.4). However, global clinical responses at 6 weeks were lower for the combination group (33% vs. 43%), which was attributed to more patients in the combination group being unevaluable for this secondary end point due to missing data.

The combination antifungal drug study, likely never to be repeated due to the substantial costs involved, suggested potential benefits for combination therapy with voriconazole and an echinocandin. For this reason, the latest guidelines¹⁷⁹ suggest consideration of but not a definitive indication for an echinocandin with voriconazole for primary therapy in the setting of severe disease, especially for patients with a hematologic malignancy and those with profound and persistent neutropenia.

Adjunctive Therapies

Reducing doses of or eliminating immunosuppressive agents, when feasible, is strongly recommended. However, IA is not an absolute contraindication to additional chemotherapy or transplantation, and the risks and benefits of the antineoplastic treatment of underlying disease must be weighed against the risk of progressive IA if treatment is delayed. According to the 2016 guidelines,¹⁷⁹ colony-stimulating factors (CSFs) may be considered for neutropenic patients, but there is insufficient evidence regarding the value of granulocyte CSF versus granulocyte-macrophage CSF in this setting. Granulocyte transfusions can be considered for neutropenic patients with IA that is refractory

or unlikely to respond to standard therapy for an anticipated duration of more than 1 week. Recombinant interferon- γ , although recommended as prophylaxis in CGD patients, is of unclear benefit as adjunctive therapy for IA.

Surgery for aspergillosis should be considered for localized disease that is easily accessible to debridement (e.g., invasive fungal sinusitis, localized cutaneous disease). The benefit for IA in other settings, such as in the treatment of endocarditis, osteomyelitis, or focal CNS disease, appears rational. Other indications are less clear and require consideration of the patient's immune status, comorbidities, confirmation of a single focus, and the risks of surgery.

Treatment for Chronic or Allergic Aspergillosis

According to the latest guidelines,¹⁷⁹ the objectives of therapy of CCPA are to improve symptoms, reduce hemoptysis, reduce progressive lung fibrosis (particularly to prevent CFPA), and prolong survival. Oral itraconazole or voriconazole is a first-line therapy, depending on tolerance and affordability.^{2,9,33,34,104} Because resistance to itraconazole during treatment has been reported more frequently than with voriconazole, for patients with a large fungal load, voriconazole may be preferable, although clinical evidence to support this approach is lacking. Posaconazole is currently third-line therapy because of the general lack of data and cost over long periods.⁷³

Treatment should be continued for a minimum of 6 months, and if well tolerated with a good response, it may be continued for years.¹¹⁹ However, toxicity may develop with long-term triazole therapy.

Monitoring of therapy is critical and should be undertaken by physicians experienced with antifungal therapy. Standard monitoring includes assessing radiographic changes (every 3 to 12 months), inflammatory markers, and *Aspergillus* IgG titers and performing annual pulmonary function tests. Susceptibility testing of isolates obtained from patients on therapy should be tested for azole resistance. Acutely ill patients who fail therapy, are intolerant of treatment, or develop azole resistance may require an initial course of intravenous antifungal therapy. Amphotericin B deoxycholate, liposomal amphotericin B, and micafungin have been extensively used for CCPA, with modest response rates.^{57,117,162}

Occasionally surgical resection is necessary for CCPA, typically for intractable hemoptysis, destroyed lung (CFPA) with poor quality of life, or azole resistance. The surgical outcomes are acceptable, but the risk of death and complications such as pleural space infection are higher for CCPA than for a single aspergilloma. Relapse rates up to 25% are documented,⁷² which makes decision making difficult, especially in the knowledge that subtle immune deficits will persist after surgery.

Because ABPA is a hypersensitivity disease, therapy centers on corticosteroids to manage the allergic component of *Aspergillus*, coupled with adjunctive oral antifungal therapy to diminish the fungal burden. Itraconazole is the best antifungal agent for this disease, and clinical trials have shown a clear benefit for itraconazole treatment of patients with ABPA, including those with CF and ABPA.²⁰⁵ Patients who fail itraconazole treatment or are intolerant of itraconazole may respond to voriconazole, posaconazole or inhaled amphotericin B.³⁸ Relapse after improvement during antifungal therapy is common; long-term suppressive therapy may be necessary. Because disease activity correlates with serum IgE levels, monitoring of IgE levels is used as one marker to define duration of therapy.

Blastomyces dermatitidis and *Blastomyces gilchristii*, the etiologic agents of blastomycosis, belong to a group of ascomycete fungi that exhibit thermal dimorphism. Other pathogens in this group include *Histoplasma capsulatum*, *Coccidioides immitis*, *Coccidioides posadasii*, *Paracoccidioides brasiliensis*, *Paracoccidioides lutzii*, *Sporothrix schenckii*, and *Talaromyces marneffeii* (formerly *Penicillium marneffeii*). In the soil (at 22°C–25°C), these fungi grow as filamentous mold that produce infectious conidia (i.e., asexual spores). After disruption of soil by activities such as construction, conidia and mold fragments that are aerosolized and inhaled into the lungs of the host (37°C) convert into pathogenic yeast.

In the yeast form, *Blastomyces* can evade immune defenses by impairing the host's cytokine and immune cell responses. In 21% to 53% of patients, infection disseminates to other organs, such as the skin or bone. Diagnosis requires a high degree of clinical suspicion coupled with the use of culture and nonculture diagnostic tests. Treatment recommendations, which were updated in 2008 by the Infectious Diseases Society of America, include the use of polyene or azole antifungal agents. Echinocandins are not effective. Selection of anti-infective therapy is influenced by disease severity, site of infection, immunosuppression, and pregnancy.

HISTORICAL PERSPECTIVE

Blastomycosis was first described as “protozoan dermatitis” by Thomas Casper Gilchrist at the 1894 American Dermatological Association meeting in Washington, DC.⁵⁹ Two years later, Gilchrist published a detailed histologic analysis of the cutaneous findings in a manuscript titled “A case of Blastomycetic Dermatitis in Man.”⁶⁰ In 1896 and 1898, Gilchrist and W.R. Stokes described a second case of blastomycetic dermatitis and named the pathologic agent *Blastomyces dermatitidis*.^{61,62}

Almost a decade later in 1907, Walter W. Hamburger analyzed four clinical isolates and described the growth of *B. dermatitidis* as mold at room temperature and as budding yeast at 37°C.⁷² During this time, heightened awareness of the disease resulted in the publication of several case reports and case series describing the clinical characteristics of blastomycosis, including invasive disease.^{110,147} Most clinical cases were from the Chicago area, and the disease became known as Chicago disease or Gilchrist disease. In early publications, two distinct forms of the disease were recognized: cutaneous and systemic.^{110,147}

In the early 1950s, Jan Schwarz and Gerald L. Baum performed a detailed clinicopathologic analysis of patients with blastomycosis and established that the primary portal of entry was pulmonary and that most cutaneous lesions were the result of dissemination from the lungs.¹³⁸ In the mid-1980s, *B. dermatitidis* caused an outbreak among children and was successfully isolated from the soil.⁸⁶ In 2013, phylogenetic analysis of 78 *Blastomyces* strains from the soil, humans, and dogs identified a new species, *Blastomyces gilchristii*.²⁵

In 2015, the sequenced genomes of *B. dermatitidis* (i.e., strains ER-3, ATCC26199, and ATCC18188) and *B. gilchristii* (i.e., strain SLH14081) were published.^{23,112} *B. dermatitidis* genes that are upregulated during infection were revealed through in vivo transcriptional profiling in a mouse model of pulmonary blastomycosis.^{98,112}

MYCOLOGY

B. dermatitidis and *B. gilchristii*, the etiologic agents of blastomycosis, are haploid ascomycetes that exhibit thermal dimorphism by growing as yeast at 37°C and as mold at 22°C to 25°C (Fig. 199.1). *Blastomyces* yeast forms (8–20 µm) are characterized by a broad-based bud (4–5 µm) and a doubly refractile cell wall.¹⁶³ This appearance is unique among

the dimorphic fungi; however, giant yeast forms (28–40 µm) have been reported, and they can be confused with *Coccidioides*.¹⁶⁴

At environmental temperatures, *Blastomyces* grows as septate hyphae (1–2 µm in diameter) capable of producing asexual spores called conidia.^{161,163} Conidia are small (4–5 µm) and are oval or piriform. Individual conidia are attached to hyphae by a short conidiophore and have the appearance of a lollipop.^{161,163} Macroscopically, yeast colonies appear off-white and can have a smooth or rough appearance. Mold colonies initially appear off-white or tan.¹⁶³ The morphologic characteristics for *Blastomyces* mold are not pathognomonic, and definitive identification requires molecular confirmation or conversion to yeast at 37°C. The conversion between mold and yeast is reversible and can be induced in the laboratory by shifting the temperature between 22°C to 25°C and 37°C.

B. dermatitidis is considered the asexual or anamorph form. The sexual or teleomorph form is known as *Ajellomyces dermatitidis*.^{104,105} In the sexual stage, *A. dermatitidis* exhibits heterothallic mating, which means that opposite mating types (+ and –) exchange genetic material to produce progeny. During mating, *A. dermatitidis* produces cleistothecia with coiled spirals that can give rise to spores known as asci. Individual asci are capable of forming hyphae with conidia (at 25°C) or converting to virulent yeast when inoculated into mice (at 37°C).^{104,105} Sexual and asexual spores and both mating types (+ and –) are capable of causing infection.^{103,106}

The genomes of clinical and environmental isolates of *B. dermatitidis* and *B. gilchristii* have been sequenced, annotated, and made available to the scientific community.^{23,112} The size of the *Blastomyces* genome ranges from 66.6 to 75.4 Mb and contains 9180 to 10,187 genes.^{23,112}

ECOLOGY AND EPIDEMIOLOGY

Blastomyces is endemic to North America and is geographically restricted to the Midwest, South Central, and Southeastern United States and several Canadian provinces (i.e., Saskatchewan, Manitoba, Ontario, and Quebec) (Fig. 199.2A). In endemic regions, *Blastomyces* spp. are not uniformly distributed but grow in an ecologic niche characterized by forested, sandy soils with an acidic pH that are located near water and contain decaying vegetation or organic matter.⁸⁶ Similar to *H. capsulatum*, a related dimorphic fungus, *Blastomyces* can grow in bird and animal excreta. Knowledge about the niche and conditions that promote growth of the mold form has been gleaned mostly from analysis of outbreaks of blastomycosis (Table 199.1). Occupational and recreational activities associated with infection involve disruption of soil and include construction of homes or roads, boating and canoeing, tubing on a river, fishing, exploration of beaver dams and underground forts, and use of a community compost pile (see Table 199.1).

Outside North America, blastomycosis is a rare cause of deep fungal infection, but autochthonous cases of culture-proven infections have been reported from India and 18 countries in Africa (see Fig. 199.2).^{7,102,139} *Blastomyces* is not considered endemic to Central America, South America, Europe, Asia, or Australia. In the developing world, the ecologic niche inhabited by *Blastomyces* spp. has not been identified. *Blastomyces* has never been isolated from soil outside North America, nor have there been human or veterinarian outbreaks to help define the geographic distribution of this pathogen in Africa or India. Compared with North American strains, African *Blastomyces* isolates display unique features, including a decreased ability to convert to yeast after a shift in temperature from 25°C to 37°C, unique media requirements for maintenance of yeast growth in vitro, and a less antigenically complex cell surface.⁸⁰

Information about the epidemiology of blastomycosis in North America is based on retrospective studies and passive surveillance. In the endemic zone, six states (i.e., Wisconsin, Minnesota, Michigan, Missouri, Arkansas, and Louisiana) and two provinces (i.e., Ontario and Manitoba) mandate reporting of new cases of blastomycosis. In North America, the annual incidence of blastomycosis ranges from 0.2 to 1.94 cases per 100,000 people (Table 199.2). Several geographic areas are considered to be hyperendemic: Kenora, Ontario (117.2 cases per 100,000 people); Vilas County, Wisconsin (40.4 per 100,000); Eagle River, Wisconsin (101.3 per 100,000); Washington Parish, Louisiana

(6.8 per 100,000); and central and south central Mississippi (more than 5 per 100,000) (see Table 199.2).

The true incidence of blastomycosis is likely much greater than the reported numbers. Reliable skin and serologic tests are not available, and about 50% of infected people develop subclinical or asymptomatic illness.⁸⁶ Epidemiologic analysis is limited to patients with clinically apparent infection that is recognized, diagnosed, and reported to public health agencies when required by law. Most epidemiologic studies show a slight male predominance for patients diagnosed with blastomycosis (see Table 199.2), which is also observed for coccidioidomycosis and histoplasmosis.

Although most patients with clinical disease have normal immune function, several medical conditions can be associated with the development of severe clinical disease, including immunosuppression due to solid organ transplantation, acquired immunodeficiency syndrome (AIDS),¹¹⁸ and treatment with medications that block the activity of tumor necrosis factor- α (TNF- α).^{134,141} A case report described severe pulmonary blastomycosis in a pediatric patient with GATA2 deficiency.¹⁴³ Most clinically recognized cases of blastomycosis are sporadic, but 17 well-defined outbreaks have been reported in North America (see Table 199.1). Among ethnicity increased susceptibility to infection according to an outbreak-related investigation in Wisconsin (see Table 199.1).¹³⁰

In the developing world, blastomycosis is found mainly in Africa and India.^{7,139} In Africa, almost 100 cases have been described from countries north and south of the equator^{7,28,51} (see Fig. 199.2B). Only a few cases have been identified from western Africa and none from

the island of Madagascar. This contrasts with *H. capsulatum* var. *duboisii*, which is endemic to western and central Africa and to Madagascar. In India, fewer than a dozen cases have been reported. Limitations in public health infrastructure and diagnostic capabilities likely contribute to underestimation of the true incidence of disease.

The clinical presentation of blastomycosis often mimics that of other pulmonary and cutaneous infections. Physicians in North America and the developing world confront a similar challenge in entertaining blastomycosis in the differential diagnosis, which is important because special stains and culture media are needed for the identification and growth of *Blastomyces*.

B. dermatitidis and *B. gilchristii* cause disease in children with normal and impaired immune defenses. Blastomycosis is uncommon in children, with an estimated 2% to 13% of cases occurring in the pediatric population.^{37,38,46,55,90,107,111} Few studies have focused solely on the pediatric population.^{3,22,47,52,123,137,144} In these studies, the average age was 9.1 to 12.9 years, with a range of 18 days to 18 years of age, and gender distribution slightly favored male predominance.^{3,22,52,47,89,123,137,144} Perinatal blastomycosis is rare, with only a few reported cases.^{37,100,159,167} In two well-described cases, the mothers developed disseminated blastomycosis (during the first and third trimesters, respectively), and the neonates were admitted to the hospital for medical care at 18 and 21 days of life.^{100,159,167} Both neonates died of respiratory failure from severe pulmonary blastomycosis.^{100,159} Similar to the neonate population, blastomycosis in infants 1 to 12 months of age is exceedingly uncommon.^{37,47,107,120,111,}

Although most cases of blastomycosis are sporadic, outbreaks are common and often result in clinical disease in children. Of the 17 reported outbreaks (see Table 199.1), 14 involved pediatric patients. The literature on pediatric blastomycosis suggests that risk of infection correlates with environmental exposure and is not influenced significantly by age or gender.¹⁵⁴

PATHOGENESIS

The ability to convert from mold to yeast is an essential event in the pathogenesis of *Blastomyces* infection and other dimorphic fungi. In the soil (at 22°C to 25°C), *B. dermatitidis* and *B. gilchristii* are thought to grow as a mold that produces infectious conidia. After disruption of soil, aerosolized conidia and mold fragments inhaled into the lungs

of a human host (at 37°C) convert into pathogenic yeast.⁵⁶ Temperature is the primary environmental stimulus that promotes this morphologic switch. The phase transition is a complex event that involves global changes in transcription, metabolism, cell signaling, cell wall composition, and plasma membrane lipid content.⁵⁶

Over the past 2 decades, the molecular tools available to genetically manipulate the dimorphic fungi have expanded and enabled the discovery of genes that affect the phase transition, including genes for dimorphism regulating kinase 1 (*DRK1*) and siderophore biosynthesis repressor in *Blastomyces* (*SREB*). *DRK1* encodes a histidine kinase that regulates the conversion of mold to yeast, production of conidia, cell wall carbohydrate composition, and expression of the essential virulence factor *Blastomyces* adhesion 1 (*BAD1*), formerly called Wisconsin 1 (*WI1*).¹¹³ Genetic deletion of *DRK1* in *B. dermatitidis* and *H. capsulatum* resulted in hyphal growth at 37°C (and 22°C), reduced transcription of *BAD1*, failure to produce conidia at 22°C, and decreased cell wall glucan.¹¹³ Moreover, *B. dermatitidis* and *H. capsulatum* with reduced *DRK1* transcripts were avirulent in a murine model of infection. These studies offered genetic proof that the conversion from mold to yeast is required for virulence of the dimorphic fungi.

SREB encodes a GATA transcription factor that promotes the conversion from yeast to mold after a drop in temperature to 22°C and regulates genes involved in iron homeostasis and lipid metabolism.^{58,97} The defect in the conversion to hyphae in *SREB*-null mutants correlates with reduction in the biosynthesis of triacylglycerol and ergosterol and with impaired homeostasis of lipid droplets, which are specialized lipid storage organelles.⁹⁷ In addition to *SREB*, *N*-acetylglucosamine (GlcNAc) accelerates the morphologic switch of *Blastomyces* (and *Histoplasma*) to hyphae, which is mediated by NGT1 and NGT2 transmembrane transporters.⁶³

B. dermatitidis and *B. gilchristii* are considered primary fungal pathogens because they cause disease in persons with intact or impaired immune defenses. Features that promote fungal growth in human tissue include the ability to survive at core human body temperature (37°C), convert to budding yeast, express yeast-phase-specific virulence factors, and evade killing by host immune cells.^{19,20,21,49,50,113,145,146} The conversion of conidia to yeast is accelerated after phagocytosis of *Blastomyces* spores by alveolar macrophages.¹⁴⁶ Yeast survive and replicate within macrophages during the early stages of infection.¹⁴⁶ This intracellular

lifestyle is similar to that of *H. capsulatum*, *Coccidioides* spp., and *Paracoccidioides* spp.

In the yeast phase, *Blastomyces* upregulates the expression of *BAD1*, which encodes a 120-kD protein that is secreted extracellularly and binds to chitin on the fungal cell wall.^{20,49,50} Deletion of *BAD1* renders *Blastomyces* nonpathogenic in a murine model of pulmonary infection, demonstrating this yeast-phase-specific virulence factor is essential for virulence.²¹ *BAD1* has multiple functions. Cell wall and soluble *BAD1* bind macrophage receptors (i.e., CR3 and CD14) to induce downregulation of TNF- α in a transforming growth factor- β (TGF- β)-dependent and -independent manner, respectively.^{20,49,50} TNF- α is a critical cytokine for host defense against *Blastomyces*; antibody-mediated neutralization of TNF- α results in progressive pulmonary infection in animal models.⁵⁰ *BAD1* impairs activation CD4⁺ T cells, which results in decreased production of interleukin-17 (IL-17) and interferon- γ (INF- γ).¹⁹ *BAD1* also facilitates adhesion of yeast to lung tissue and T cells through interaction with heparan sulfate,^{16,19} binds exogenous calcium,¹⁸ and impedes binding of complement (C3) to the yeast cell surface.¹⁶⁹

Blastomyces yeast also secrete dipeptidylpeptidase IVA (DPPIVA), which impairs recruitment and differentiation of inflammatory monocytes by cleaving host chemokines.¹⁴⁵ The loss of recruited inflammatory monocytes (and differentiated cells) to the lung enhances the virulence of *Blastomyces* yeast.¹⁴⁵ DPPIVA also cleaves granulocyte-macrophage colony-stimulating factor (GM-CSF), which promotes intracellular survival in macrophages and blunts neutrophil antifungal activity.¹⁴⁵

Changes in cell wall carbohydrate composition associated with the phase transition may contribute to virulence and immune evasion. During the conversion from mold to yeast, the amount of α -(1,3)-glucan increases and that of β -(1,3)-glucan decreases. *Blastomyces* mutants deficient in α -(1,3)-glucan have impaired virulence in a murine model of infection.⁷³ Similarly, reduction or complete loss of α -(1,3)-glucan synthase activity in *H. capsulatum* renders this dimorphic fungal pathogen avirulent.¹²⁷ The concentration of cell wall β -(1,3)-glucan drops from 40% to 50% in mycelia to less than 5% in yeast.⁷⁷ Exposed β -(1,3)-glucan binds mannose-binding lectins (i.e., MBL-A and MBL-C).⁸⁷ Collectively, these events may block the recognition of *Blastomyces* β -(1,3)-glucan by the Dectin-1 receptors on innate immune cells (i.e., macrophages). Moreover, the reduction of β -glucan in the yeast cell wall precludes the use of the (1 \rightarrow 3)- β -D-glucan test for diagnosis and of echinocandins for treatment of blastomycosis.^{32,65}

To combat infection, the innate and adaptive immune responses are required, whereas humoral immunity is dispensable. After inhalation of aerosolized conidia, alveolar macrophages phagocytize and kill a large percentage of conidia and regulate transformation to the pathogenic yeast phase.^{43,148,149} Neutrophils also can ingest and kill conidia.⁴³ Conidia that survive the initial assault by macrophages and neutrophils germinate into yeast. *Blastomyces* yeast cells are more difficult to kill because they fail to induce a robust oxidative response, are relatively resistant to reactive oxygen species, and suppress nitric oxide production in macrophages.¹²⁹

The adaptive immune response, which is coordinated by T lymphocytes, is important for controlling infection in a manner that requires helper T-cell type 17 (Th17) responses (i.e., IL-17) and helper T-cell type 1 (Th1) cytokine responses (i.e., interferon- γ and TNF- α) to activate macrophages to enhance fungicidal activity and promote clearance.^{17,165} After infection, patients develop specific cellular immunity to that persists for at least 2 years.⁸¹

CLINICAL MANIFESTATIONS

The heterogeneous clinical manifestations of blastomycosis range from asymptomatic infection to acute pneumonia to disseminated disease. The lung is the primary portal of entry for aerosolized conidia and mycelial fragments after disruption of soil. After evasion of pulmonary host defenses, *B. dermatitidis* can remain localized in the lung or disseminate to other organs. Less common routes of transmission in children include direct cutaneous inoculation and inhalation of infected vaginal secretions at birth.^{100,159,167,168} Definitive evidence for transplacental transmission to the fetus is lacking but is theoretically possible; *Blastomyces* yeast have been isolated from placental tissue.⁹³ Transmission

of *Blastomyces* through solid organ transplantation (i.e., infected allograft) has not been reported, but this route of transmission has been described for *H. capsulatum* and *Coccidioides* species.⁹⁶

Based on studies during an epidemic,^{85,86} onset of symptomatic (acute pulmonary) disease occurs 3 weeks to 3.5 months after exposure to *B. dermatitidis* or *B. gilchristii*.

Pulmonary Disease

Acute pneumonia is the most common clinical manifestation of blastomycosis, and symptomatic disease develops in approximately 50% of infected children.⁸⁶ Clinical manifestations resemble community-acquired pneumonia and include fevers, chills, headache, cough (which is often productive), dyspnea, chest pain, and malaise.^{47,123,154,166} Severity of disease ranges from mild illness that can be managed in the outpatient setting to acute respiratory distress syndrome (ARDS) requiring intubation and mechanical ventilation.^{3,38,57,84,86,123} Chronic pneumonia can develop and is often associated with extrapulmonary dissemination and a delay in diagnosis.^{47,137,144}

The lung is the most common organ affected by *Blastomyces* and is involved in 79% to 86% of patients with symptomatic blastomycosis.^{3,38,47,52,143,166} Consolidation, which can be unilobar, multilobar, or diffuse, is the most frequent radiographic pattern described for children with pulmonary blastomycosis (Fig. 199.3).^{2,47,84,86,123,137} Consolidation from blastomycosis is indistinguishable from bacterial pneumonia. Nodular and interstitial infiltrates are the second and third most common findings on chest radiography, respectively.^{2,46,47} Hilar lymphadenopathy, pleural effusion, and lung abscess are infrequently encountered (Fig. 199.4).^{2,47,84,123} Cavitory disease and mass lesions are rare in children and can mimic tuberculosis or neoplasm.

After treatment of pulmonary blastomycosis, radiographic abnormalities can persist for several years, and functional pulmonary deficits (i.e., restrictive or obstructive disease) can be slow to normalize in patients with severe disease.^{1,2,123} Fortunately, most patients experience a full recovery without long-term pulmonary sequelae.¹

Disseminated Disease

After infection is established in the lung, *Blastomyces* can disseminate to almost any organ in the body. Based on retrospective studies, disseminated disease in children occurred in 21% to 53% of sporadic cases,^{3,22,47,52,137} which is similar to the rate for adults with blastomycosis

FIG. 199.3 Chest radiograph of a right upper lobe infiltrate due to blastomycosis.

FIG. 199.4 Computed tomography of the chest reveals consolidation and abscess formation in the right lower lobe of the lung.

FIG. 199.5 Verrucous lesion of blastomycosis on the face of a child.

(25–40%).³² In contrast, dissemination with acute pulmonary blastomycosis associated with point-source outbreaks occurred in a minority of patients.¹⁵⁴ The time from symptom onset to diagnosis is often delayed in patients who are diagnosed with disseminated disease.^{47,137} Collectively, these data suggest that the duration of infection rather than age influences the risk for dissemination.¹⁵⁴

Disseminated blastomycosis most commonly affects the skin and bone.^{47,143,166} Cutaneous disease often begins as papulopustular lesions and progresses to ulcerative, verrucous, or crusted lesions (Figs. 199.5 and 199.6).¹⁶⁶ Erythema nodosum, which is common in patients with histoplasmosis and coccidioidomycosis, is rare in cases of blastomycosis.¹⁶⁶ Skin involvement can be associated with underlying osteomyelitis and manifests as pustules, abscesses, and ulcers (Figs. 199.7 and 199.8).¹¹⁴ Invasion of *Blastomyces* into the bone results in lytic destruction that is often associated with a periosteal reaction and a sclerotic margin.¹¹⁴ Although any bone can be infected, the most common sites include the long bones (e.g., tibia, humerus), skull, ribs, and vertebral bodies (Figs. 199.9 and 199.10).^{47,114,131,166}

Clinical manifestations of osteomyelitis include bone pain and soft tissue swelling associated with a draining sinus, ulcer, or abscess.¹¹⁴ Vertebral osteomyelitis can be complicated by extension into the soft tissues, resulting in paravertebral and psoas abscesses or invasion of the adjacent intervertebral disks and vertebral bodies.¹³¹ These features

FIG. 199.6 Crusted skin lesion on the nose caused by *Blastomyces*.

can mimic *Mycobacterium tuberculosis* (i.e., Pott disease).¹¹⁴ Progressive destruction of vertebral bone can result in compression fractures.¹³¹ Similarly, osteomyelitis of the long bones can be complicated by pathologic fracture or extend into the joint space to cause septic arthritis.^{89,114}

Blastomycosis rarely disseminates to the central nervous system (CNS) or other organs such as the liver, spleen, heart, or middle ear.^{38,52,74,76,166} Otitis media from blastomycosis is an uncommon complication related to contiguous extension from an extra-auditory focus into the middle ear.^{48,76} CNS blastomycosis is estimated to occur in less than 5% to 10% of nonimmunocompromised patients and results from hematogenous spread or direct invasion from untreated infection of the scalp or skull.^{38,47,90} CNS blastomycosis manifests as meningitis, epidural abscess, or brain abscess involving the cerebrum or cerebellum (Fig. 199.11).^{10,47,90} Some patients have concomitant meningitis and brain abscess.¹⁰ Complications include hydrocephalus, mass effect from edema, cerebral herniation, infarction, seizures, panhypopituitarism, residual weakness, and impaired ability to function at school.^{10,47} In patients with meningitis, cerebrospinal fluid (CSF) demonstrates a lymphocytic or neutrophilic pleocytosis associated with elevated protein levels and hypoglycorrhachia.¹⁰ Forty-five percent of CSF cultures grow *B. dermatitidis*.¹⁰

Disease in Immunocompromised Patients

Information regarding the clinical course and treatment outcomes for blastomycosis in children with impaired immunity is limited to a few

FIG. 199.11 Computed tomography of the brain demonstrates a multiloculated abscess in the right temporal lobe as a result of infection with *B. dermatitidis*.

case reports.^{141,157,168} Clinical studies have investigated blastomycosis in adults who have undergone solid organ transplantation, developed AIDS, or been diagnosed with malignancy.^{57,70,118,119,152} Blastomycosis is estimated to occur in less than 0.2% of solid organ allograft recipients and manifests 0.4 to 250 months after transplantation, occurring in an almost equal distribution before and after the first year of transplantation.^{57,70} Infection most commonly causes pneumonia, which is often complicated by respiratory failure or ARDS.^{57,70} The frequency of extrapulmonary infection (33–50%) is similar to that in the general population (25–40%).^{32,57,70} The mortality rate is 33% to 38%, but it increases to 67% for patients with ARDS.^{57,70,119}

Blastomycosis in patients with AIDS is uncommon, and a single case series of 15 patients was published before the use of highly active antiretroviral therapy (HAART) that systemically investigated *Blastomyces* infection in this patient population.¹¹⁸ The lung was infected in 87% of patients, and extrapulmonary disease occurred in 53%.¹¹⁸ Invasion of *Blastomyces* into the CNS was common and occurred in 40% of patients. This clinical profile sharply contrasts to that of patients immunosuppressed by transplantation or malignancy, among whom the incidence of CNS blastomycosis is similar to that in the general population (<5–10%).^{57,70,90,119} Approximately two thirds of AIDS patients with blastomycosis had prior opportunistic infections. The CD4⁺ T-lymphocyte count at the time of diagnosis of blastomycosis was often less than 200 cells/mm³.¹¹⁸ The mortality rate attributable to blastomycosis was 53%.¹¹⁸

Blastomyces can infect patients with hematologic or solid organ malignancies, including those with lung carcinoma, squamous cell cancers of the head and neck, breast cancer, gastrointestinal neoplasms, chronic lymphocytic leukemia, acute myelogenous leukemia, Hodgkin disease, and multiple myeloma.^{119,152} Similar to allograft recipients and those with AIDS, pneumonia was the most common clinical manifestation and was complicated by ARDS in some patients.¹¹⁹ Extrapulmonary disease occurred in approximately 50%.¹¹⁹ The high mortality rate was attributable to the underlying malignancy or blastomycosis.¹¹⁹

Blastomycosis is a rare complication for patients receiving TNF- α inhibitors.^{29,101,134,141} In 2008, the US Food and Drug Administration issued an alert stating that patients taking TNF- α blockers such as etanercept, adalimumab, infliximab, and certolizumab are at risk for endemic mycoses, including histoplasmosis, coccidioidomycosis, and blastomycosis.²⁹ In this alert, seven cases of blastomycosis were reported. An analysis of health claims information from 2007 to 2009 with 30,772 unique patients who received TNF- α blockers identified 253 infections in 158 people, with only 4% due to blastomycosis.¹³⁴ However, no clinical

data were provided about the patients with blastomycosis. The clinical information about blastomycosis in patients on TNF- α inhibitors is limited to a few case reports.^{101,141}

Blastomycosis During Pregnancy and in Neonates

Blastomycosis is a rare complication of pregnancy, and clinical information is limited to sporadic case reports.^{13,37,91} Women can be infected in any trimester, but the disease is most frequently diagnosed in the second or third trimester.^{13,37,91} Disseminated disease is common (62%) and often involves the lungs, bone, and skin.⁹¹ Isolated pulmonary infection occurs in 38% of patients.⁹¹ Reliable information regarding the frequency of placental involvement is lacking because examination by histology or culture has been performed in only one third of clinical cases. However, dissemination to the placenta is possible.^{91,93} Histologic analysis identified *B. dermatitidis* yeast in the placenta of a 23-year-old woman with pulmonary blastomycosis complicated by ARDS during the third trimester.⁹³ Her infant was delivered by cesarean section and did not develop blastomycosis.⁹³

Although clinical data are limited, blastomycosis during pregnancy does not appear to increase the risk for congenital malformations. However, based on isolation of *Blastomyces* yeast from the placenta of one mother and two well-described clinical cases of neonatal blastomycosis, there is potential for transmission of blastomycosis during the peripartum period.^{93,100,159} Both infants were admitted to the hospital for respiratory failure at 18 and 21 days of life. Infection was limited to the lungs, and both infants died of progressive pulmonary blastomycosis.^{100,159} The underlying pathogenesis of neonatal blastomycosis is not well defined and may involve transplacental transmission or aspiration of infected vaginal secretions.

DIAGNOSIS

The diagnosis of blastomycosis requires a high index of suspicion because clinical and radiographic manifestations can mimic other diseases, including bacterial pneumonia, mycobacterial infections, and neoplasms. A detailed history focusing on potential exposures for the acquisition of *Blastomyces* can facilitate diagnosis in a timely fashion. The delay between symptom onset and diagnosis often exceeds 2 months.^{47,137,144} Risks factors for endemic fungal infections include outdoor activities (i.e., canoeing, hiking, beaver dam exploration), home remodeling, construction (e.g., residential, commercial, road), playing in outdoor forts, hunting, fishing, use of a woodpile for a wood burning stove, and employment in a microbiology laboratory (see Table 199.1).^{52,69,88}

The diagnosis of blastomycosis in a household pet, frequently a dog, suggests a common source of exposure.^{5,13,15,24,52,64,108} Canine blastomycosis can serve as a harbinger of human blastomycosis.¹³⁶ In a retrospective analysis of 111 children with blastomycosis, 8.1% of patients had a dog with blastomycosis.⁵² Airborne transmission of *Blastomyces* between animals and humans does not occur; however, primary cutaneous blastomycosis has been reported from bite injuries.^{66,69} Microbiology laboratory workers are at risk for cutaneous infection from injuries caused by sharp implements such as needles.^{69,88}

Diagnostic evaluation for blastomycosis should be considered for patients with pneumonia or cutaneous lesions that fail to respond to antibiotic therapy. Pneumonia identified on chest radiography and cutaneous lesions on physical examination strongly suggest blastomycosis.

Definitive diagnosis of blastomycosis requires identification of *Blastomyces* in culture from sputum, skin, bone, or other clinical specimens. Commonly used culture media include Sabouraud dextrose agar and potato dextrose agar.¹³² For culture of tissue specimens, supplementation of medium with brain-heart infusion agar is recommended.¹³² Incubator temperatures used in most clinical laboratories (25°C–30°C) promote the growth of *Blastomyces* as mold. Because several other fungal species have a similar appearance, additional confirmatory tests are required, which can include use of chemiluminescent DNA probes that target specific rRNA sequences, polymerase chain reaction (PCR) assay, and conversion to yeast at 37°C.¹³²

A presumptive diagnosis of blastomycosis can be made when yeast forms (8–20 μ m) with broad-based budding and a doubly refractile

FIG. 199.12 Overwhelming infection with *B. dermatitidis* is demonstrated in lung tissue with a silver stain.

cell wall are visualized by light microscopy from respiratory secretions, purulent material, or histopathologic sections. Visualization of *Blastomyces* requires special stains such as 10% potassium hydroxide, calcofluor white, Gomori methenamine silver (GMS), periodic acid–Schiff (PAS), or Papanicolaou (Fig. 199.12).⁹⁰ *Blastomyces* yeast can be difficult to visualize using Gram staining or hematoxylin and eosin stains. Neutrophilic infiltration with noncaseating granulomas (i.e., pyogranulomas) in tissue specimens can suggest the diagnosis of blastomycosis and should prompt detailed microscopic examination for *Blastomyces* yeast.

For patients with pulmonary disease, specimens can be obtained from sputum, tracheal aspirate, bronchoscopy with bronchoalveolar lavage (BAL), or open-lung biopsy. Sputum cultures can be diagnostic for *Blastomyces* in up to 75% of patients⁹⁹; however, sputum specimens tend to be more useful in older patients because collection of high-quality sputum can be difficult to obtain in young children.¹³⁷ If sputum cannot be obtained or is nondiagnostic, a tracheal aspirate or bronchoscopy with BAL can be performed. Although the diagnostic yield for BAL has been reported as 92%, results in the pediatric population may be suboptimal because of technical limitations.^{99,137} If specimens obtained from sputum and BAL fail to demonstrate *Blastomyces* and clinical suspicion remains high, open-lung biopsy is required. In some case series¹³⁷ but not others,⁴⁷ lung biopsy was needed for diagnosis of most children.

Nonculture diagnostic techniques are often used in conjunction with fungal smear and culture to facilitate the diagnosis of blastomycosis. An antigen test against a galactomannan component of the *Blastomyces* cell wall has become an important adjunctive test. Specimens for antigen testing can be collected from the urine, serum, BAL fluid, and CSF, but robust clinical data exist only for urine and serum specimens.^{9,36,44} Sensitivity for the urine antigen test ranges from 76.3% to 92.9% and is influenced by the burden of infection.^{9,36,53} For patients with localized pulmonary disease, sensitivity decreases to 50%, whereas for those with diffuse pulmonary disease, sensitivity increases to 87.5%.⁹ Antigen levels tend to be higher in those with ARDS than those without.³⁶ Serum *Blastomyces* antigen sensitivity is 57% to 81.8%.^{9,36} Because there is substantial cross-reactivity with *H. capsulatum* (96%), *P. brasiliensis* (100%), and *P. marneffei* (70%), the specificity of the antigen test is 76.9% to 79%.^{9,44} Cross-reactions sometimes cause diagnostic difficulties because *Histoplasma* and *Blastomyces* exist in similar endemic regions in North America. However, this does not usually affect clinical management because treatment recommendations for blastomycosis and histoplasmosis are similar.^{32,160} Diagnostic confusion related to cross-reactions with *P. brasiliensis* or *P. marneffei* are uncommon, unless the patient has resided in or visited Central or South America or Southeast Asia, respectively. Urine antigen detection has been successfully used in the pediatric population for diagnosis and monitoring the response to antifungal therapy.^{53,109}

Classic serologic studies such as complement fixation (CF), immunodiffusion (ID), and enzyme immunoassays (EIA) have been largely

supplanted by the *Blastomyces* antigen test. Although the specificity for CF and ID assays range from 97% to 100%, the sensitivity is 9% and 28%, respectively.⁸⁵ EIA has a sensitivity of 77% with a specificity of 92%.⁸⁵ All three serologic tests detect antibodies against the A antigen found in the *B. dermatitidis* cell wall. A radioimmunoassay for the BAD1 surface protein has a sensitivity of 85% and specificity of 98%, but the test is not commercially available.⁸³ A EIA that uses microplates coated with BAD1 protein has a sensitivity of 87% and specificity of 94% to 99% for patients with active blastomycosis.¹²⁸ Combined BAD1 EIA and antigen testing increased diagnostic sensitivity to 97%.¹²⁸ The BAD1 antibody EIA test is expected to become commercially available.

Molecular diagnostic assays using real-time PCR to amplify *BAD1* and *DRK1* genes have been developed, but they are not commercially available.^{6,140}

TREATMENT

Treatment of blastomycosis is influenced by the severity of the infection, presence or absence of CNS dissemination, integrity of the immune system, and pregnancy (Table 199.3).³² Antifungal therapy is recommended for all patients diagnosed with blastomycosis, including those with resolution of clinical symptoms before receiving therapy.³² Although spontaneous resolution of symptomatic blastomycosis has been reported,¹³⁵ the frequency of this phenomenon remains unknown. Moreover, dissemination to organs such as the skin and CNS can occur after the spontaneous resolution of pulmonary disease. Because 31% to 53% of children with blastomycosis develop disseminated disease,^{3,22,47,52,137} the decision to withhold therapy for pulmonary blastomycosis can be dangerous and lead to extrapulmonary spread of infection. The goal of therapy for patients with spontaneous resolution of acute pulmonary blastomycosis is to prevent extrapulmonary blastomycosis.³²

For children with mild to moderate pulmonary blastomycosis, itraconazole in a dosage of 10 mg/kg per day (maximum, 400 mg/day) for 6 to 12 months of therapy is recommended (see Table 199.3).³² For children with severe pulmonary blastomycosis (including ARDS), treatment consists of induction with amphotericin B for 1 to 2 weeks and consolidation with itraconazole (10 mg/kg per day; maximum, 400 mg/day) for 12 months (see Table 199.3).³² Recommended

amphotericin B formulations include amphotericin B deoxycholate (0.7–1 mg/kg per day) or liposomal amphotericin B (3–5 mg/kg per day).³² Children tolerate the deoxycholate formulation better than adults.³²

Treatment recommendations for children with impaired immunity from human immunodeficiency virus (HIV) infection or AIDS, transplantation, or malignancy involves induction therapy with amphotericin B followed by consolidation with itraconazole (see Table 199.3).³² For some immunosuppressed patients, lifelong suppression may need to be considered if immune suppression cannot be reversed.³² Specific recommendations regarding criteria for suppressive therapy are lacking, and the decision is left to the health care provider. Most adult transplant recipients adequately treated for blastomycosis do not experience relapse, and lifelong suppressive therapy is used only in selected patients.^{57,70} Whether these clinical observations of adult transplant recipients are directly applicable to immunosuppressed pediatric patients is unknown.

Children with mild to moderate disseminated blastomycosis are treated with itraconazole in a dosage of 10 mg/kg per day (maximum, 400 mg/day) for 6 to 12 months (see Table 199.3).³² Patients with severe disseminated disease are treated in a similar manner as those with severe pulmonary disease. This includes induction therapy with amphotericin B for 1 to 2 weeks followed by 12 months of itraconazole.³²

Treatment of CNS blastomycosis requires a prolonged course of liposomal amphotericin B at 5 mg/kg per day for 4 to 6 weeks followed by high-dose azole antifungal therapy for at least 12 months.³² Liposomal amphotericin B is the preferred formulation because of its superior CNS penetration compared with amphotericin B lipid complex (ABLC) or amphotericin B deoxycholate.^{32,71} Recommended azoles include fluconazole (800 mg/day), itraconazole (200 mg two to three times daily), or voriconazole (200–400 mg twice daily).³² The most effective azole for CNS disease remains to be determined.

Fluconazole has excellent CSF penetration (52–82% of serum levels), but minimal inhibitory concentrations are higher than those with itraconazole or voriconazole.^{68,78} Itraconazole has been successfully used to treat some cases of CNS blastomycosis despite its poor penetration into the CSF at less than 10% of serum.^{32,78} In contrast, voriconazole levels in the CSF are 38% to 68% of serum, and minimal inhibitory concentrations are similar to those of itraconazole.^{68,78} There are several case reports of successful use of voriconazole to treat adults with CNS fungal infections, including blastomycosis.^{8,150} Surgical

TABLE 199.3 Treatment of Blastomycosis in Children and Pregnant Women

Condition	Drug of Choice	Dosage	Duration
Pulmonary Blastomycosis			
Mild to moderate	Itraconazole	10 mg/kg/day ^a	6–12 mo
Severe or life-threatening	Amphotericin B deoxycholate	0.7–1 mg/kg/day	1–2 wk
	Lipid amphotericin B	3–5 mg/kg/day	1–2 wk
	Itraconazole ^b	10 mg/kg/day ^a	12 mo
Extrapulmonary (Non-CNS) Blastomycosis			
Mild to moderate	Itraconazole	10 mg/kg/day ^a	6–12 mo
Severe or life-threatening	Amphotericin B deoxycholate	0.7–1 mg/kg/day	1–2 wk
	Liposomal amphotericin B	3–5 mg/kg/day	1–2 wk
	Itraconazole ^b	10 mg/kg/day ^a	12 mo
Immunocompromised patient	Amphotericin B deoxycholate	0.7–1 mg/kg/day	1–2 wk
	Liposomal amphotericin B	3–5 mg/kg/day	1–2 wk
	Itraconazole ^b	10 mg/kg/day ^a	12 mo
CNS blastomycosis	Liposomal amphotericin B	5 mg/kg/day	4–6 wk
	Itraconazole ^c	400–600 mg/day	12 mo
	Fluconazole ^c	800 mg/day	12 mo
	Voriconazole ^c	400–800 mg/day	12 mo
Pregnant patient	Liposomal amphotericin B	3–5 mg/kg/day	
Neonate	Amphotericin B deoxycholate	1 mg/kg/day	

^aMaximal dose of 400 mg/day.

^bItraconazole should be started after at least 1 to 2 weeks of therapy with amphotericin.

^cItraconazole, fluconazole, or voriconazole should be started after at least 4 to 6 weeks of therapy with amphotericin. CNS, Central nervous system.

debridement should be considered for patients with intracranial masses, epidural abscesses, cranial osteomyelitis, and spinal osteomyelitis with instability.¹⁵⁸

Pediatric patients of childbearing age with blastomycosis should undergo pregnancy testing before initiation of antifungal therapy. High-dose and prolonged treatment with triazoles increases the risk for fetal deformities and spontaneous abortion.^{11,41,122,126,156} Administration of fluconazole to pregnant patients diagnosed with *C. immitis*, a dimorphic fungus related to *Blastomyces*, resulted in skeletal and craniofacial defects resembling Antley-Bixler syndrome (i.e., trapezoidocephaly–multiple synostosis syndrome).¹²⁶ Voriconazole and posaconazole can cause skeletal abnormalities in animal models.^{122,156} Several human studies have demonstrated that itraconazole increases the risk of spontaneous abortion.^{11,41} To minimize harm to the developing fetus, liposomal amphotericin B (3–5 mg/kg per day) is recommended.^{32,35}

After delivery, the placenta should be examined histopathologically for *Blastomyces*. The neonate should be carefully assessed for infection and clinically monitored for the clinical signs and symptoms of blastomycosis. Amphotericin B deoxycholate (1 mg/kg per day) is the recommended antifungal agent for treatment of neonatal blastomycosis.³²

Effective clinical management of patients with blastomycosis requires efforts to minimize toxicity, avoid drug-drug interactions, optimize bioavailability, and monitor drug levels. Amphotericin B deoxycholate and its lipid formulations are fungicidal against *Blastomyces* and achieve high rates of clinical cure.³³ However, these agents require intravenous administration, are nephrotoxic, and promote urinary wasting of potassium, magnesium, and bicarbonate. Hydration with normal saline before and after therapy with amphotericin and use of lipid-associated formulations can minimize the risk for nephrotoxicity.¹³³ Replacement of potassium and magnesium losses is needed in most patients. Bicarbonate replacement is rarely required. Frequent monitoring of electrolytes and creatinine is needed for patients receiving amphotericin.³²

In contrast to amphotericin B, azole antifungal agents are fungistatic against *Blastomyces*, and clinical efficacy varies among the available agents. In a prospective, nonrandomized, open-label trial, itraconazole (200–400 mg/day) resulted in a 90% cure rate.⁴² Itraconazole is available in capsule and liquid formulations. Absorption of the capsule formulation is enhanced with gastric acidity and coadministration with food.^{32,40} The liquid formulation (100 mg/10 mL) has 30% better bioavailability than the capsule formulation and should be administered without food.^{32,40}

Fluconazole is less efficacious than itraconazole and is not recommended by the 2008 guidelines published by the Infectious Diseases Society of America for pulmonary or non-CNS disseminated blastomycosis.³² If fluconazole is used for treatment, 400 to 800 mg/day dosing is required to optimize clinical response. The success rate for 400 to 800 mg/day dosing was 87%, whereas it was 65% for 200 to 400 mg/day.^{116,117} Approximately 50% of patients who received high-dose fluconazole experienced adverse events, including alopecia, xerosis, and elevated results of liver function tests.¹¹⁷ Similar to fluconazole, ketoconazole is no longer recommended for the management of blastomycosis.³²

The newest triazoles—voriconazole, posaconazole, and isavuconazole—have in vitro activity against *Blastomyces*.^{68,67} Although clinical experience with voriconazole, posaconazole, and isavuconazole is limited, several case reports suggest that they can be an effective treatment option.^{8,115,125,150,151} To optimize bioavailability, voriconazole needs to be administered in the fasting state, whereas posaconazole liquid suspension requires coadministration with fatty foods and avoidance of proton pump inhibitors or histamine-2 (H_2) receptor blockers.^{122,156} Posaconazole delayed-release tablets and isavuconazole capsules can be administered without regard to food or stomach acidity. Voriconazole, posaconazole, and isavuconazole can also be administered parentally.

Therapeutic drug monitoring for itraconazole is recommended after steady-state levels are achieved, which is at the end of the second week of therapy. Given the long half-life of itraconazole (i.e., 24 hours), serum levels can be obtained independent of the time the drug was administered.³² Goal therapeutic levels are more than 1 $\mu\text{g/mL}$ (i.e., itraconazole and hydroxy-itraconazole levels are added together).³² Serum concentrations greater than 10 $\mu\text{g/mL}$ are not needed and can increase the risk of side effects. Therapeutic drug monitoring can also be performed for voriconazole; goal serum levels are between 1.0 and 5.5 $\mu\text{g/mL}$.⁴

In addition to therapeutic monitoring, liver function tests should be assessed at baseline, at 2 and 4 weeks into therapy, and then every 3 months for all azoles.³² Careful review of all medications is needed to avoid drug-drug interactions with azoles. This is especially important for patients who are immunosuppressed by organ transplantation or receiving pharmacologic therapy for seizures.

Debridement for osteomyelitis or abscesses is not considered curative, and antifungal agents should always be administered after surgical intervention. Moreover, the duration of antifungal therapy should not be shortened.

Patients diagnosed with blastomycosis do not require isolation because person-to-person transmission through aerosols or respiratory droplets has not been reported. Standard barrier precautions (i.e., gloves) are needed in caring for patients with open wounds.

In the last 2 decades of the previous century, *Candida* species emerged as major human pathogens.^{26,86,331,340} The increase in invasive candidiasis (IC) was likely the result of an expanding population of patients with immune systems compromised by prematurity, immunomodulatory therapies, and chemotherapeutic agents. Increased use of broad-spectrum antimicrobial therapy, administration of parenteral nutrition, and placement of invasive devices probably further contributed to a growing population of persons who are highly susceptible to IC. Although data suggesting a decline in IC at pediatric institutions in the United States are encouraging,²⁵⁴ *Candida* remains the most common cause of invasive fungal disease and the second most common cause of central line-associated bloodstream infections (BSIs) in US health care settings. Furthermore, IC results in substantial attributable mortality rates among neonates and children with significant increases in health care resource use.^{279,337} This chapter discusses the epidemiology, pathogenesis, clinical manifestations, diagnosis, and management of IC in the pediatric population. Because of notable differences in the pathogenesis, presentation, and management of IC in neonates, neonatal candidiasis is discussed separately.

ORGANISM

Candida spp. comprise a heterogeneous group of eukaryotic, diploid organisms that grow predominantly with yeast morphology (i.e., unicellular). Most members are able to produce pseudohyphae; however, only *C. albicans* and *C. dubliniensis* are able to produce true hyphae, thus making them the only polymorphic *Candida* species. *Candida* spp. are commensal organisms, commonly found in the gastrointestinal and genitourinary tracts of healthy humans. More than 150 species have been described; of these, more than 20 different species are associated with infection in humans.^{48,130,277} *C. albicans* is the most frequent species isolated from humans; other more commonly isolated pathogenic species include *C. parapsilosis*, *C. tropicalis*, *C. glabrata* (previously known as *Torulopsis glabrata*), and *C. krusei*. Less commonly, IC may be caused by *C. guilliermondii*, *C. lusitanae*, *C. dubliniensis*, *C. pelliculosa*, *C. kefyr*, *C. rugosa*, *C. famata*, *C. norvegensis*, *C. orthopsilosis*, *C. metapsilosis*, *C. nivariensis*, and *C. inconspicua*.

Candida spp. grow on routine agar and do not require special fungal media for isolation. The appearance of *Candida* colonies may vary from cream to yellow in color, with a texture that may vary from smooth to wrinkled, glistening or dry, depending on the species. Under optimal growth conditions, yeast grow in log phase as unicellular budding yeast forms (blastospores) that are spherical to ovoid and measure 2.5 to 6 µm in diameter.^{122,277} Pseudohyphae are polarized growths that form when budding daughter cells remains attached to the parent cell wall, thereby forming elongated, often branching forms with constricted septal junctions between cells. In contrast, true hyphae are formed from yeast cells or as branches from existing hyphae and are characterized by defined septa that divide the hyphae into separate fungal units. True hyphae can be a feature of some *Candida* species such as *C. albicans* and *C. dubliniensis*. Growth of *Candida* hyphae can be precipitated in the presence of serum at 37°C and at pH 7.^{184,277,293} Germ tube formation is a precursor to hyphae, and the presence of germ tube formation has been used to inform a presumptive identification of *C. albicans*, although false-positive and false-negative results may occur.^{136,275}

Identification of the most common *Candida* species is possible on the basis of carbohydrate assimilation and fermentation testing, in addition to morphology. The use of commercially available kits such as API 20C AUX (bioMérieux-Vitek), the Auxacolor2 (Sanofi Diagnostics Pasteur), and the Uni-Yeast Tek kit (Remel Laboratories)

use changes in turbidity or the production of color through enzymatic reactions to create specific biochemical profiles that permit the rapid identification of the more common *Candida* spp.⁸⁷ Chromogenic agar (e.g., CHROMagar *Candida*, Becton Dickinson), which incorporate substrates linked to chemical dyes in a solid medium, allows for presumptive identification of clinically important *Candida* spp. including *C. albicans* (green smooth colonies), *C. tropicalis* (metallic blue colonies with a pink halo), *C. krusei* (pale rose flat colonies), and *C. glabrata* (white or purple smooth glistening colonies), although misidentification of less common *Candida* spp. as *C. glabrata* has been reported.^{87,136,238} Chromogenic agar permits identification in as early as 24 to 48 hours and is particularly valuable in detecting coinfection with different *Candida* spp., which may be ordinarily missed during conventional subculture on solid medium.^{87,277}

EPIDEMIOLOGY

Candida is the most important cause of fungal infection in health care settings. It broadly affects a growing population of immunocompromised patients, in addition to patients with critical illness, prematurity, or complex chronic conditions. The incidence of IC in the United States has risen since the 1970s, with rates of nosocomial BSI with *Candida* quadrupling between 1980 and 1989.²⁴ An increase in adult candidemia-related hospitalizations was sustained in the United States between 2000 and 2005.³⁴⁰ More recent publications have suggested a decline in IC among both pediatric and neonatal populations throughout the first decade of this century.^{61,65,99} The cause of this decline is not known but is likely multifactorial and hypothesized to be related to improved adoption of infection control initiatives and use of targeted antifungal prophylaxis in high-risk groups. Nonetheless, data from the National Healthcare Safety Network still show *Candida* spp. as the second most common cause of central line-associated BSIs in the United States.²⁷⁶

IC is of particular concern in the pediatric population given its potential to cause significant morbidity and mortality. Crude mortality rates in children with candidemia range from 10% to 26%, with an attributable mortality rate of candidemia in children estimated to be 10%.^{43,189,223,291,336,337} Evidence of dissemination has been estimated to occur in 8.3% to 17% of children with candidemia,^{43,84,96,306,335} with organ involvement most commonly occurring in the lungs (45.2–58%), liver (23%), kidney (16%), brain (12%), heart (8–22.3%), spleen (8%), and eyes (3.2–8%).^{84,335,339} In addition to severe clinical outcomes, candidemia in children results in a prolonged length of inpatient stay and considerable increase in monetary expenditures.³³⁷

C. albicans is the predominant *Candida* species colonizing the gastrointestinal genital mucosa and the mucous membranes of 30% to 60% of humans.¹⁸⁴ Not surprisingly, *C. albicans* is the most common cause of invasive fungal disease in children; however, on the basis of international data, non-*C. albicans* species now account for more than half of IC episodes in children.²⁹¹ Furthermore, the epidemiology of non-*albicans* species differs among children as compared with adults. Specifically, *C. parapsilosis* is the second most common species isolated from children with IC. International prospective pediatric cohort studies have identified *C. parapsilosis* in 22% to 34% of IC episodes,^{223,291} thus corroborating the epidemiologic findings from single-center pediatric studies.^{81,189,288,339} Experimental animal models have demonstrated that *C. parapsilosis* is associated with reduced virulence compared with that of *C. albicans* and *C. tropicalis*,³²⁷ and clinical studies have also shown higher rates of treatment success in children and reduced mortality rates in adults with *C. parapsilosis* invasive disease compared with other *Candida* spp.^{223,291}

Understanding the distribution of *C. glabrata* and *C. krusei* is necessary given their reduced susceptibility to triazole antifungal agents. *C. glabrata* exhibits variable susceptibility to fluconazole, with well-described cross-resistance with the extended spectrum triazoles,²³² whereas *C. krusei* is intrinsically resistant to fluconazole, with most isolates susceptible to voriconazole.^{233,234} The epidemiology of *C. glabrata* differs between adults and children. In adults, *C. glabrata* accounts for more than one-fourth of the IC events,^{43,137,223} but less than 9% of pediatric cases.²²¹ *C. krusei* is similarly infrequent in all age groups.

C. tropicalis is an infrequent cause of IC in children and predominantly occurs in oncologic populations.¹⁷⁵ Data from animal models indicate that *C. tropicalis* is similar in virulence to *C. albicans*, although *C. tropicalis* has been associated with an increased propensity for dissemination in neutropenic hosts than has *C. albicans*.^{172,175}

Several cohort studies have been performed to elucidate specific risk factors for the development of IC in children. In a single-center case-control study examining risk factors for candidemia in a children's hospital, cases were more likely to occur in children with central venous catheters, use of topical antifungal agents before candidemia, and longer exposure to hyperalimentation compared with controls; however, only unadjusted analysis was performed, limiting interpretation of the results.¹⁸⁹ A single-center population-based case-control study examined risk factors for candidemia in pediatric patients admitted to a pediatric intensive care unit.³³⁹ On multivariable analysis, receipt of vancomycin or an antimicrobial agent with anaerobic activity for 4 days or longer was both independently associated with a significant increased risk of candidemia (adjusted odds ratio [OR], 6.19; 95% confidence interval [CI], 2.40–15.99; and adjusted OR, 3.51; 95% CI, 1.47–8.38, respectively). Other significant risk factors included malignant disease (OR, 4.02; 95% CI, 1.23–13.11) and the presence of a central venous catheter (adjusted OR, 30.45; 95% CI, 7.76–119.49). Receipt of hyperalimentation was found to be significantly associated with candidemia on unadjusted analysis, but the association became nonsignificant after inclusion into the multivariable model.

Leveraging these individual risk factors, a clinical prediction rule was derived inclusive of the following factors: vancomycin, anaerobic-spectrum antibiotics, malignant disease, presence of a central venous catheter, and hyperalimentation. Children with three or more risk factors had between 10% and 46% predicted probability of developing candidemia.³³⁹ Similar risk factors of the presence of central venous catheters, arterial lines, hyperalimentation, prolonged antibiotic exposure, and antibiotic exposure were identified in another study performed in a population of pediatric intensive care patients.⁹⁷ Unfortunately, an attempt to validate the aforementioned clinical prediction rule failed in a multicenter cohort. This failure highlights the challenges of leveraging factors that vary across institutions for a one-size-fits-all clinical prediction rule.¹⁰⁰

Risk factors for disseminated candidiasis in children have been examined by several investigators.^{84,95,335} In a case-control study of children with candidemia, persistently positive blood cultures for *Candida*, more than 3 days with a central venous catheter in place, and immunosuppression (neutropenia, use of immunosuppressant medications, or history of bone marrow transplant) were found to be independent risk factors for the development of disseminated candidiasis.³³⁵ Another case-control study of children with candidemia identified receipt of vasopressors, prolonged candidemia (≥ 3 days) after central venous catheter removal, and neutropenia to be independently associated with disseminated candidiasis.⁸⁴ Similarly, in an unadjusted analysis of children hospitalized with candidemia, prolonged candidemia and the presence of an immunocompromising condition were found to be associated with dissemination.⁹⁵ Risk factors for mortality among pediatric patients have also been examined, with location in a pediatric intensive care unit at the time of infection, the presence of an arterial catheter, tracheal intubation, and neutropenia significantly associated with death.^{223,336} With the exception of neutropenia, these risk factors are likely markers for severe illness.

Finally, investigators have studied risk factors for infection, specifically with *C. glabrata* and *C. krusei*, given the increased azole resistance among these pathogens. Age older than 2 years, recent surgical procedure, and prior fluconazole exposure were each identified as independent risk factors for infection from these species in children.²³⁹

PATHOGENESIS

Pathogen Factors

The virulence of a pathogen is an important determinant of the ability of a microorganism to inflict host cell damage and cause disease. Virulence factors have been best studied in *C. albicans* likely because this species is the most common cause of IC and is thought to be the most pathogenic.²⁷⁷ Consequently *C. albicans* serves as the prototype for this discussion of virulence factors, with exceptions noted for other non-*albicans* *Candida* species where relevant. The pathogenicity of *C. albicans* is mediated by several virulence factors, including adhesion, biofilm formation, secretion of hydrolytic enzymes, and morphology switching, thus permitting it to become the most successful opportunistic fungal pathogen in humans.

The obligatory first step in the establishment of colonization and subsequent host invasion is the adherence of *C. albicans* to host surfaces and medical devices. Adherence is essential for initiating and maintaining a commensal relationship with the host,²⁵⁵ and it is mediated by adhesion biomolecules present at the fungal surface that permit binding to host cells and host-cell ligands. Agglutinin-like sequence proteins (Als) are the most widely expressed adhesins in *C. albicans* and encode a group of glycosyl-phosphatidyl-inositol (GPI)-anchored proteins localized on the outer cell wall layer.³⁰⁵ Among all Als proteins, Als1p, Als3p, and Als5p appear to play major roles in adherence to host cells.³⁰⁵ Hyphal wall protein 1 (Hwp1p) is found exclusively at the germ tube surface and is another important adhesin, mediating tight binding to buccal epithelial cells.²⁸⁷ Cell wall carbohydrates such as glycosylated mannoproteins and sialic acids may also contribute to adherence.³⁰⁵ Among non-*C. albicans* species, *C. tropicalis* has been shown to produce Als proteins, whereas *C. glabrata* has been found to produce a group of adhesins encoded by the EPA (epithelial adhesin) gene family. Cell wall adhesin-like proteins have also been discovered in *C. parapsilosis*, although further work on the virulence associated with these proteins is limited.²⁷⁷

Biofilm formation is an important mechanism of virulence for several *Candida* species, including *C. albicans*, *C. parapsilosis*, *C. tropicalis*, and *C. glabrata*.²⁷⁷ The capacity to establish a biofilm plays a significant role in infections involving medical devices such as central venous catheters, urinary catheters, cardiovascular devices, and prosthetic implants.^{23,169} *Candida* biofilms are complex communities of yeast, pseudohyphae, and hyphae encased in a self-produced extracellular matrix. The formation, structure, and composition of the biofilm depend on the nature of the contact surface, environmental factors, and *Candida* species, the last of which can dictate ability to switch morphology from yeast to hyphae.^{209,277} Several studies have demonstrated that biofilm growth can dramatically enhance resistance to antifungal agents. Minimum inhibitory concentrations (MIC) of amphotericin B, flucytosine, fluconazole, itraconazole, and ketoconazole against *C. albicans* growing in biofilms have all been shown to be significantly higher (up to 2000 times higher) than the MIC in planktonic *C. albicans*.^{129,176,244,299} Investigators have suggested that biofilm-associated *Candida* acquire resistance because of a low growth rate and decreased drug penetration through the matrix; however, certain studies have not supported these conclusions.^{4,18} Instead, antifungal resistance is thought to be conferred by contact-dependent upregulation of genes encoding efflux pumps during the course of biofilm formation, although multiple mechanisms may contribute to antifungal resistance of the *Candida* biofilm.^{208,245}

Production of extracellular hydrolytic enzymes is an essential aspect of the pathogenicity of *Candida* species, facilitating tissue invasion by disruption of the host mucosal membranes and by degrading important immunologic and structural proteins, including IgG heavy chains, α_2 -macroglobulin, β -lactoglobulin, C3 protein, lactoperoxidase, collagen, and fibronectin.^{236,277} The three most important hydrolytic enzymes produced by *Candida* are the secreted aspartyl proteinases (Saps), phospholipase B enzymes, and lipases.^{211,277} The Sap proteins are encoded by a family of 10 SAP genes and are considered key determinants of *Candida* virulence, with level of Sap activity in vitro appearing to correlate with the virulence of *C. albicans*, *C. tropicalis*, and *C. parapsilosis*.²¹¹ Data are limited on the capacity of *C. glabrata* to produce proteinases.

Morphologic conversion between yeast and hyphal forms is believed to play an important role in the dissemination and tissue invasion of

C. albicans. Initial experiments using animal models suggested that the hyphal form represented the pathogenic state of the organism because mutant strains lacking hyphae exhibited impaired ability to invade tissue compared with wild-type *C. albicans*.^{57,187} Subsequent data demonstrating constitutively filamentous mutant strains as avirulent led to the hypothesis that it was not the morphologic form per se, but rather the ability to undergo morphology switching, that contributed to the pathogenicity of *C. albicans*.⁴⁴ More recently, a mouse model of hematogenously disseminated candidiasis using a mutant *C. albicans* strain that permitted external modulation of morphology switching demonstrated that both yeast and hyphae were important stages in the development of IC.²⁶⁶ Saville and coinvestigators²⁶⁶ were able to demonstrate in a mouse model of disseminated candidiasis that mice injected with this strain under conditions permitting hyphal development succumbed to infection, whereas all mice injected under conditions inhibiting the formation of hyphae survived, thus indicating that filamentous formation was a critical factor in pathogenicity. However, fungal burdens were almost identical in animals injected with strains under hyphae-permitting and hyphae-repressing conditions, a finding suggesting that yeast forms were important for initial extravasation and dissemination in the host. Interestingly, histopathologic examination of kidneys recovered from mice exposed to hyphae-repressing conditions revealed no significant damage despite organ invasion, with all the invading fungal cells present only in yeast form.²⁶⁶

Host Factors

As previously noted, *Candida* spp. can cause infection in almost any anatomic location in either localized or disseminated presentations. The immune responses to these different compartments are distinct, as evidenced by the differing clinical presentations depending on a patient's risk factors and underlying immune compromise. Both innate and adaptive arms of the immune system play key roles in the immune response to *Candida* and are influenced by the site of infection. A detailed discussion of the host immune response to *Candida* is beyond the scope of this chapter, but several excellent reviews are available for more in-depth coverage.^{70,119,312}

The initial host response to infection with *Candida* involves recognition of pathogen-associated molecular patterns (PAMPs) present on the fungal cell wall.³¹² Pattern recognition receptors (PRR) on the surface of innate immune cells perform this function, and several classes of PRR have been identified in the induction of innate host responses to *Candida*, including the Toll-like receptors (TLRs), the C-type lectin receptors (CLRs), and the NOD-like receptors (NLRs).¹¹⁹ Recognition of yeast and hyphae morphologic features is differential, with each form recognized by different host receptors.^{80,311} TLR2, TLR4, and TLR9 have all been implicated as having key roles in recognition of *Candida* and induction of proinflammatory cytokines.³¹² CLRs comprise a large family of receptors with a shared ability to recognize microbial polysaccharides, and they are thought to be the most important PRR family in the recognition of fungi.¹¹⁹ Within this family, dectin 1, dectin 2, macrophage mannose receptor 1, dendritic cell-specific intercellular adhesion molecule 3 (ICAM3)-grabbing nonintegrin (DC-SIGN), and soluble mannose-binding lectin serve to recognize *C. albicans* and are involved in phagocytosis, production of inflammatory cytokines, neutrophil recruitment and activation, and complement activation.^{119,312} Finally, NLRs located within the cytoplasm function to activate inflammasomes (protein platforms that induce the activation of interleukin [IL]-1 β and IL-18 through caspase 1) and may have an important role in T-helper 1 (T_H1)-type and T_H17-type responses against *C. albicans*, important for containing disseminated and mucosal infection, respectively.^{313,319}

Beyond the role of PRRs in the innate immune response to *Candida*, neutrophils, macrophages, and monocytes are all critically important antifungal effector cells, as evidenced by the high risk of disseminated disease in neutropenic patients.^{54,84,144,335} Phagocytes already residing in infected organs are involved in the killing of invading *Candida*, whereas neutrophils and monocytes are recruited to the site of infection. The large size of hyphae may preclude engulfment of *Candida* by these phagocytes; however, studies have demonstrated the important role of neutrophil extracellular traps (NETs) in the killing of both hyphal and yeast forms.^{309,310}

The adaptive immune system plays a critical role in protecting against oropharyngeal candidiasis. Until recently, protective adaptive responses were thought to be mediated by CD4⁺ T_H1 effector cells. However, with the discovery in 2005 of a subset of CD4⁺ T_H17 cells,^{127,178,227} investigators found that T_H17-type responses play a crucial role in controlling *C. albicans* at the mucosa.^{70,119} This finding is supported by the observation that patients with chronic mucocutaneous candidiasis (CMC), either as isolated autosomal dominant CMC (AD-CMC) or as part of a primary immunodeficiency secondary to hyperimmunoglobulin E syndrome (HIES) or autoimmune polyendocrinopathy with candidiasis and ectodermal dystrophy (APECED), share a common defect related to an inadequate T_H17 response. The major genetic defect causing HIES is a mutation in the gene encoding STAT3 transcription factor, resulting in impaired T_H17 differentiation.⁷⁰ Most patients with AD-CMC have a defect in the STAT1 gene, which is involved in the IL-23/IL-23-R pathway crucial for induction of T_H17 responses. The mechanism of susceptibility to *Candida* infection in patients with APECED has been linked to neutralizing autoantibodies against T_H17-type cytokines in affected patients.^{165,241}

With respect to hematogenously disseminated candidiasis, the portal of entry of *Candida* into the host bloodstream has been the source of much debate, with both the gastrointestinal tract and the skin proposed as the source of acquisition. In a remarkable experiment performed in 1969, an investigator ingested 10¹² *C. albicans* cells and underwent serial blood and urine sampling. After experiencing a transient febrile reaction with chills, *C. albicans* was isolated from the blood and urine within 3 hours of ingestion, thus forming the only experimental human evidence to support the gut as a source of candidemia.¹⁷⁴ Animal models of candidal gut colonization and subsequent development of disseminated candidiasis after immunosuppression also support an intestinal source for candidemia.^{210,264,308} In a systematic review of the literature investigating skin or intestinal colonization as the source of candidemia, the investigators identified more compelling data in support of intestinal colonization as the primary source.²¹⁵ This conclusion is consistent with findings of anaerobic spectrum antibiotics as significant risk factors for candidemia³³⁹ because antibiotics with anaerobic activity have been shown to permit a higher and more sustained increase in intestinal colonization with yeasts.²⁶³ However, other portals of entry besides the intestines are important for the development of IC, as evidenced by the increased incidence of candidemia in patients with burn injury²³⁰ and in patients requiring intravascular devices.¹⁶⁹

The Damage Response Framework (DRF) has been proposed as a novel construct to classify the interaction of a microbe and the host because it relates to the clinical presentation of infection in the host.⁵⁰ The DRF has six classifications that depend on whether the microbe is causing an infection in a host at a time when the immune system is weakened or robust. The details of this construct are beyond the scope of this chapter; however, the DRF has been used to explain the variety of clinical infections that result from *Candida* species such as oropharyngeal candidiasis, vulvovaginal candidiasis, candidemia and disseminated candidiasis, and intra-abdominal candidiasis.¹⁴³ More details on each of these clinical manifestations are provided in the following sections.

CLINICAL MANIFESTATIONS

Infections with *Candida* spp. have myriad presentations and depend largely on the immune status of the host as well as the existence of predisposing risk factors. The clinical manifestations of candidiasis in the neonatal population are unique and are discussed separately. Given the differences in pathogenesis of candidal diseases, the following discussion is subdivided into superficial (mucocutaneous) and invasive disease manifestations.

Superficial Candidiasis

Oropharyngeal Candidiasis

Oropharyngeal candidiasis is one of the most common manifestations of *Candida* infection. Pediatric populations in which oropharyngeal candidiasis can be seen most frequently include young infants, patients with primary or acquired immunodeficiency, and patients receiving

chemotherapy for malignant diseases. Additionally, occurrence in healthy children with other risk factors (e.g., inhaled corticosteroid exposure,¹⁰⁹ broad-spectrum antibiotic exposure²⁸⁶) is not uncommon.

The most common manifestation of oropharyngeal candidiasis in children is pseudomembranous candidiasis, or thrush. Pseudomembranous candidiasis is characterized by the presence of white to creamy plaques on the buccal mucosa, tongue, and gums, although less frequently the soft palate, uvula, and tonsils may also be involved. These lesions may be associated with pain and dysphagia, although frequently they are asymptomatic.³¹⁴ These adherent plaques may be removed by gentle scraping, which discloses an erythematous base. Histologic examination of these membranes reveals epithelial cells together with yeast and filamentous forms of *Candida*.³³⁰ Aside from pseudomembranous candidiasis, other forms include erythematous atrophic candidiasis and angular cheilitis. Erythematous atrophic candidiasis most frequently manifests as painful erythematous lesions on the dorsum of the tongue and palate, although the buccal mucosa may also be involved. This form is commonly associated with prior broad-spectrum antibiotic exposure and may spontaneously resolve once antibiotics are discontinued and normal bacterial flora is restored.³³⁰ Angular cheilitis may appear alone or in conjunction with pseudomembranous or erythematous atrophic candidiasis, and it is characterized by painful erythema and fissuring at the angles of the mouth. *C. albicans* is the most common species isolated, although *C. tropicalis*, *C. parapsilosis*, and *C. glabrata* may also be seen.^{34,111,142,201,218}

Esophageal Candidiasis

Esophageal candidiasis is most commonly seen in severely immunocompromised children and is an acquired immunodeficiency syndrome–defining illness in children infected with human immunodeficiency virus (HIV). Similar to oropharyngeal candidiasis, other risk factors include immunosuppression related to malignant disease, transplantation, or primary immunodeficiency, in addition to corticosteroid exposure (inhaled or systemic) and broad-spectrum antibiotics.^{13,17,123,145,167,270} Although esophageal candidiasis is frequently accompanied by oropharyngeal candidiasis, the absence of oral involvement does not exclude *Candida* esophagitis. In a case-series of HIV-infected children receiving highly active antiretroviral therapy, 28% of *Candida* esophagitis episodes were not associated with concomitant oropharyngeal candidiasis.⁶⁰ Common presenting symptoms include odynophagia, retrosternal or epigastric pain, and dysphagia, although in severely immunocompromised children fever may occasionally occur.^{59,60,314} Findings on endoscopic examination include the presence of white plaques, erythema, and edema of the esophageal mucosa, ulceration, and, in severe cases, strictures. *Candida* spp. may be cultured from endoscopic brushings, although positive isolation does not distinguish infection from commensal *Candida* colonization. Reliable diagnosis may be made by histologic evidence of tissue invasion in biopsy material.³¹⁴ In addition to esophageal endoscopy, barium contrast studies of the esophagus may reveal findings of shaggy mucosal irregularities and nodular filling defects suggestive of esophageal candidiasis, although other radiographic patterns can be seen.^{116,180,181}

Vulvovaginal Candidiasis

Vulvovaginal candidiasis is extremely rare before menarche, but it increases in frequency during late adolescence and adulthood. Between 50% and 70% of women may be diagnosed with this condition during their lifetime.^{104,285} Risk factors for the development of vulvovaginal candidiasis include diabetes mellitus, pregnancy, oral contraceptives, glucocorticoid exposure, and broad-spectrum antibiotics.^{2,118,283} Unlike in other mucosal sites of *Candida* infection, HIV seropositivity is not a clear risk factor for vulvovaginal candidiasis, although rates of *Candida* vaginal colonization have been shown to be significantly higher in HIV-seropositive versus HIV-seronegative at-risk women.^{2,269} Common symptoms include vaginal pruritus, erythema, dysuria, and an odorless, thick, white, curdlike discharge.⁷ The diagnosis can be clinically supported by identification of yeast and pseudohyphae or hyphae seen with potassium hydroxide or saline on microscopy, although the sensitivity of microscopy varies between 38% and 83%.⁷ Isolation of *Candida* from culture of vaginal secretions does not differentiate infection from colonization.

Cutaneous Candidiasis

Cutaneous candidiasis occurs in moist, occluded cutaneous sites that promote maceration of the skin and superficial invasion by *Candida*. Diaper dermatitis is a common manifestation that typically occurs in infants, with peak prevalence during the second to fourth months of life.¹³⁵ The lesions of *Candida* diaper dermatitis generally erupt in the perianal area, spreading to involve the perineum and inguinal folds, with confluent erosions, satellite pustules on an erythematous base, and marginal scaling. Evidence of *Candida* colonization in the stool is present in up to 90% of children,²⁴⁷ a finding suggesting that the gastrointestinal tract is the most important source for *Candida* diaper dermatitis. Oropharyngeal candidiasis is accompanied by diaper dermatitis in 34% to 52% of patients, thus indicating that diaper dermatitis may be the result of successive oral and gastrointestinal colonization.¹³⁵ Cutaneous candidiasis may also manifest as intertrigo occurring in the inframammary, axillary, inguinal, perineal, intergluteal, and interdigital regions. Lesions may appear as pustules on an erythematous base with central confluence, satellite lesions, and associated pruritus and tenderness.³³² Folliculitis and balanitis are less common presentations of cutaneous infection.

Chronic Mucocutaneous Candidiasis

CMC is a clinical syndrome characterized by persistent or recurrent *Candida* infections of the oropharynx, skin, nails, and, uncommonly, esophagus and larynx.^{164,168} In some patients, chronic localized *Candida* granulomas may occur, manifesting as thick, adherent, hyperkeratotic “wartlike” lesions on the scalp and face.^{164,332} Rather than a single entity, CMC is a manifestation of several heterogeneous disorders unified largely by a common downstream defect in a mucosal *Candida*-induced T_H17-type response,¹¹⁹ although some exceptions exist. CMC can manifest as an isolated disease (autosomal dominant CMC) or as part of a primary immunodeficiency disorder such as HIES, APECED, severe combined immunodeficiency, dedicator of cytokinesis 8 (DOCK8) deficiency, and deficiencies of IL-12, IL-17, and IL-23.³¹⁷ CMC typically appears in infancy or early childhood and may be associated with recalcitrant or relapsing candidal disease despite antifungal therapy. Despite extensive cutaneous and mucosal involvement, reports in the literature of IC are rare for children with CMC.

Invasive Candidiasis

Candidemia

The clinical manifestations of candidemia may vary from nonspecific signs of fever and malaise to septic shock and multiple organ dysfunction syndrome.¹⁷⁰ Additional manifestations may be apparent as a result of dissemination through the bloodstream to distal sites including the central nervous system (CNS) and musculoskeletal system, the lungs, the eyes, and the abdominal viscera, with the risk of dissemination increasing with the number of days of blood culture positivity and immunosuppression.^{1,335}

Acute Disseminated Candidiasis

Endovascular candidiasis. Endovascular candidiasis manifests most commonly as infective endocarditis, although septic thrombophlebitis and mycotic aneurysm are less frequently seen.^{204,265} *Candida* may be the most common cause of health care–associated infective endocarditis in children; a single-center study reported isolation of *Candida* spp. from 27% of children with nosocomial infective endocarditis.¹⁹⁶ Previous reports suggested an increasing rate of *Candida* endocarditis,^{298,253} although no published data commenting on recent trends are available. Clinical manifestations are similar to those of non-*Candida* endocarditis and may include fever, onset of a new or changing murmur on auscultation, hepatosplenomegaly, and congestive heart failure, in addition to the embolic and immunologic phenomena seen with infective endocarditis. Transthoracic or transesophageal echocardiography may reveal the presence of an intracardiac thrombus or valvular vegetations.

Risk factors cited for *Candida* endocarditis include prematurity, congenital or acquired heart defects or endovascular prostheses, the presence of a central venous catheter, immunosuppression, broad-spectrum antibiotic exposure, and hyperalimentation.^{204,298} In a literature review of pediatric *Candida* endocarditis, the frequency of involvement

of right-sided intracardiac structures (e.g., right atrium, tricuspid valve) was three times that of left-sided structure for patients with a reported site of intracardiac lesion.²⁰⁴ This finding likely reflects the contributory role of central venous catheters as both a source of endothelial trauma and a portal of entry of *Candida* in the development of this complication.

Cardiac candidiasis. *Candida* spp. may be a rare cause of pericarditis and myocarditis in children.³²³ At least six cases of pediatric *Candida* pericarditis and five cases of *Candida* myocarditis have been reported in the English literature.^{73,268,323} *Candida* pericarditis and myocarditis may occur in the setting of recent cardiothoracic surgical procedures, contiguous focus of pleural or mediastinal infection, contiguous intracardiac spread of infection (e.g., *Candida* endocarditis), or acute hematogenous dissemination.^{268,323} Clinical symptoms of *Candida* pericarditis may be subtle but include fever, chest pain, and dyspnea, with evidence of pericardial rub and cardiac tamponade on examination, enlarged cardiac silhouette on chest radiography, and ST-T-wave changes on electrocardiography. Blood culture results may not be positive, thus complicating early recognition.^{73,323} Echocardiography reveals the presence of pericardial effusion. Candidal invasion and necrosis of the myocardium may be extensive and produce associated signs of congestive heart failure, with electrocardiographic changes suggestive of myocarditis.³²³ Mortality rates in the literature have been high, with only 1 of 11 patients with reported pediatric *Candida* pericarditis and myocarditis having survived. The high mortality rate may have reflected the lack of recognition of *Candida* as the origin because the diagnosis was made postmortem in the majority of these cases.^{73,268,323}

Pulmonary candidiasis. Two different patterns of invasive pulmonary candidiasis have been described: primary *Candida* bronchopneumonia and secondary pulmonary disease in the setting of disseminated candidiasis.^{126,151,228} Primary *Candida* bronchopneumonia is limited largely to immunocompromised patients and infants and is thought to occur by aspiration of *Candida* into the upper respiratory tract. In autopsy studies of adults with invasive pulmonary disease with no other sites of dissemination or antemortem candidemia, a distinct pattern of intra-alveolar hemorrhage, alveolar exudates, necrosis, and microabscesses with evidence of *Candida* may be present, with several cases also showing evidence of esophageal candidiasis.¹²⁶ A similar pattern was seen in autopsies of three infants with evidence of airspace IC concurrent with colonization of the upper respiratory tract and oropharynx.¹⁵¹ Although *Candida* species are often cultured from respiratory specimens taken from critically ill patients, this finding typically represents colonization rather than true infection.³³³ Only a small subset of patients with a positive respiratory specimen for a *Candida* species will have *Candida* bronchopneumonia.²⁶⁷ Histologic demonstration of invasion of *Candida* within lung tissue is the only widely accepted criterion for the definitive diagnosis of primary *Candida* bronchopneumonia.²⁸ However, lung biopsy is not always possible to establish the diagnosis definitively, thereby making it difficult to know which patients should receive antifungal therapy. In general, antimycotic therapy for *Candida* bronchopneumonia should be reserved for patients with underlying immunocompromise, respiratory failure, and evidence of pneumonia without growth of another pathogen.

More commonly, invasive pulmonary candidiasis occurs as a secondary consequence of hematogenous dissemination in a patient with candidemia or from showering of septic thrombi from an infected central venous catheter, septic thrombophlebitis, or *Candida* endocarditis. In disseminated candidiasis, secondary pulmonary involvement is typically capillary invasive, with bilateral lung involvement. On microscopic examination pseudohyphae are seen to invade the pulmonary capillaries, arterioles, and small arteries and thus enter the lung parenchyma. Microabscesses may be present in the lungs as well as in other end-organ sites of dissemination. In embolic pulmonary candidiasis the lungs are seeded with infected emboli from an endovascular source, with resulting hemorrhagic infarcts in the periphery of the lungs and septic thrombi in the small and medium-sized pulmonary arteries. Extrapulmonary thrombi may also be seen in other sites.¹⁵¹

Secondary pulmonary candidiasis may be suspected in the setting of candidemia or other sites of disseminated disease. The radiographic appearance of secondary pulmonary involvement typically consists of

multiple 3- to 30-mm nodules scattered throughout the lung parenchyma with consolidation found in advanced disease. Histologically these lesions have areas of central necrosis with pseudohyphae and budding yeast. Cavitation is not typically seen.^{46,151,228}

Candidiasis of the peritoneum, gastrointestinal tract, and gallbladder. The most common cause of *Candida* peritonitis is peritoneal dialysis (PD)-associated peritonitis; other causes include perforation of an intra-abdominal viscus or surgery-related peritonitis resulting from an anastomotic leak. Fungal peritonitis has been reported to occur in 3% of all peritonitis episodes in children undergoing PD, with *Candida* spp. comprising most causes of fungal peritonitis.^{206,243,325} Similar to other *Candida* health care device-associated infections, colonization or biofilm formation of the PD catheter is the presumed nidus of infection, and thus catheter removal is often an important component of source control. Early removal of the PD catheter has been associated with improved outcomes in adults.⁵³ Common presenting signs and symptoms include fever and abdominal pain; sepsis with hemodynamic instability may also be seen, although extraperitoneal dissemination is rare. An elevated leukocyte count of greater than 100/mm³ in the dialysate may be seen, whereas Gram stain may reveal budding yeast forms. Culture of the dialysate allows identification of the organism. Recent administration of systemic antibiotics has been consistently noted to be a risk factor for the development of PD-associated fungal peritonitis.^{243,325} Outcomes are generally good, with a low mortality rate in children of 0% to 6% compared with the 13% to 53% mortality seen in adults. In addition, 50% to 70% of children are able to continue PD after treatment for fungal peritonitis.^{243,325}

IC of the lower gastrointestinal tract is an uncommon but previously described entity in severely immunocompromised patients, although the literature has been limited to the adult population.^{63,202,296,240} Clinical manifestations include invasive candidal enterocolitis with or without pneumatosis and infarction. Patients may present with fever, acute abdominal pain, distention, emesis, and bloody diarrhea. Grossly, hemorrhagic ulcerations and nodules may be seen, occasionally with transmural infarction. White plaques may be seen and mistaken for pseudomembranous colitis. On histopathologic examination, periodic acid-Schiff and Gomori methenamine silver stains may reveal budding yeast and filamentous forms invading the mucosa and submucosa.

In addition to peritonitis and intestinal IC, *Candida* has also been described to cause acalculous candidal cholecystitis, as well as biliary obstruction resulting from *Candida* mycetoma.^{49,202}

Candidiasis of the urinary tract. In the majority of asymptomatic persons without a urinary catheter, the presence of yeast in the urine indicates contamination or colonization. The clinical significance of candiduria in the setting of an indwelling urinary catheter is less clear because *Candida* in the urine may signify either a catheter-associated urinary tract infection (UTI) or simply colonization and biofilm formation of the catheter in the absence of true infection. A repeat urine specimen from a newly placed catheter can help to distinguish candiduria from colonization of the catheter. Urinalysis should also be performed because the presence of pyuria, hematuria, or leukocyte esterase may be useful in distinguishing infection from colonization. However, longstanding catheters can elicit an abnormal urinalysis. Clinical manifestations of *Candida* UTI may be indistinguishable from those of bacterial UTIs, with dysuria, frequency, urgency, and, in the setting of pyelonephritis, fever and flank pain. In patients with indwelling catheters, symptoms may be less recognizable, either because of a lack of dysuria or as a result of sedation status that impedes the patient's ability to communicate symptoms in the intensive care unit, although suprapubic discomfort may be reported.¹⁵²

In patients who are symptomatic, imaging with renal ultrasonography is the preferred modality for identifying renal parenchymal abnormalities resulting from ascending infection and for detecting urinary tract obstruction if present. Renal mycetomas may appear as hyperechoic, nonshadowing foci, whereas renal abscesses may appear as hypoechoic masses.^{45,246} Other imaging modalities used to identify pyelonephritis, renal abscesses, and renal mycetomas include computed tomography (CT), magnetic resonance imaging (MRI), and renal cortical scintigraphy.

In patients with candidemia, isolation of *Candida* in the urine may signify infection from hematogenous seeding of yeast to the renal

parenchyma, with subsequent development of renal abscesses, renal mycetomas (fungus balls), collecting system obstruction, and renal failure. In the setting of hematogenous seeding of the renal parenchyma, a urine culture may yield relatively low colony counts of *Candida*.¹⁵² Patients with this clinical presentation should have further imaging such as renal ultrasonography to assess the renal parenchyma.

Osteoarticular candidiasis. *Candida* osteomyelitis is not common but is a well-described form of IC with *Candida* seeding the bone by hematogenous dissemination, direct inoculation, or contiguous infection.¹¹⁰ Risk factors cited include the presence of a central venous catheter, a history of preceding candidemia, prior surgical intervention, broad-spectrum antibiotics, and immunosuppression.^{110,278} The most common sites of involvement in children are (in descending order) the femur and humerus, with rib, vertebra, and sternum involvement much more infrequent. This is in contrast to adults, in whom the vertebra is the most common site of infection. Involvement of more than one site is common; 83% of cases in one study had two or more bones infected.¹¹⁰ The clinical presentation of *Candida* osteomyelitis is indolent, with presenting symptoms lasting several weeks to months. Fever is less common, but most patients have tenderness with erythema or edema. Draining sinus tracts are common and are more likely to occur with nonvertebral osteomyelitis (32%). Laboratory markers such as erythrocyte sedimentation rate and C-reactive protein level are commonly elevated. Imaging with radionuclide scanning may reveal multiple sites of involvement; MRI may reveal bone destruction, soft tissue extension, and abscess formation, with decreased signal intensity on T1-weighted imaging and increased signal intensity on T2-weighted imaging.¹¹⁰ However, inflammatory markers and imaging findings are nonspecific, and thus, in the absence of candidemia, a biopsy of the involved site with culture and histopathology stains may be necessary to secure the diagnosis.

Up to 85% of cases of pediatric fungal arthritis occur in infants younger than 6 months of age.²⁹⁴ Arthritis concomitant with bone involvement has been reported to occur in 11% to 80% of cases, with the most common synovial joints infected being the knee (11%) and hip (5%).^{89,110,294} Infection often originates from the bloodstream, with seeding of the synovium or metaphyseal vessels resulting in septic arthritis and osteomyelitis, respectively. *Candida* septic arthritis has been reported to manifest several months to a year after the initial episode of candidemia.^{128,294} Although two-thirds of patients may have acute symptoms of fever and painful swelling of the joint, *Candida* arthritis may also manifest indolently. Arthrocentesis of the affected joint should be performed for diagnostic and therapeutic reasons. The synovial fluid typically reveals a with a neutrophilic predominant leukocyte count that can range from 7500 to 151,000/mm³; *Candida* may be isolated from cultures of the synovial fluid. Histopathologic examination of the synovium may reveal a nonspecific mononuclear inflammatory infiltrate with thickening of the synovium. In contrast to other fungal arthritides, granuloma formation is uncommon with *Candida* arthritis.^{89,294}

Central nervous system candidiasis. *Candida* infection of the CNS can involve any part of the brain or spinal cord and manifests as acute or chronic meningitis, ventriculitis, microabscesses, or macroabscesses. Fortunately, CNS involvement is not common. In a large international case series of culture-proven IC, only 1% of pediatric patients and 4% of neonates had a positive cerebrospinal fluid (CSF) culture result for a *Candida* species.²²⁰ CNS involvement is typically the result of hematogenous spread; up to 66% of patients with *Candida* infection of the CNS have a recent or concurrent positive blood culture result at the time of diagnosis.^{124,200,335} Involvement of the CNS through direct inoculation at the time of surgery or through infection of intracranial device (e.g., ventriculoperitoneal shunt, external ventricular drain) may also occur. Neonates, patients with hematologic malignant disease, hematopoietic transplant recipients, and neurosurgical patients are at increased risk for CNS disease; thus heightened clinical suspicion is needed in these patient populations.^{113,124,200}

The clinical manifestations of CNS candidiasis vary depending on the patient population and the type of involvement. Importantly, profound immunosuppression with neutropenia and consequent limited ability to mount an inflammatory response may lead to subtle symptoms in oncologic patients and transplant recipients with candidal meningitis and brain abscesses. A single-center case series of 12 children with

leukemia and candidal meningitis highlighted the subtle nature of this serious infection in immunocompromised patients. Among the 12 patients, 42% had fever as their only sign of systemic infection, and only 50% exhibited an altered level of consciousness.²⁰⁰ Similarly, in a case series of 19 pediatric and adult bone marrow transplant recipients with *Candida* brain abscesses, only 42% had altered mental status, 26% had cranial nerve abnormalities, and 16% had seizures. Headache, papilledema, nausea, and vomiting were uncommon, and nearly one-third had no signs or symptoms, with diagnosis being made postmortem.¹²⁴ In both studies, the findings of CSF analysis were often unremarkable, with at least one-half of subjects in each series lacking pleocytosis and with mildly elevated protein levels and hypoglycorrhachia found in only a minority of patients. In those with CSF pleocytosis, a neutrophilic predominance is typically seen,^{10,69,124,188} although a mononuclear predominance may be present in neutropenic patients.²⁰⁰ MRI appears to be more sensitive than CT in the detection of brain abscesses; however, 60% of patients with *Candida* brain abscesses may have normal scans, likely related to the difficulty in detecting microabscesses on imaging. *Candida* frequently produces multiple brain lesions, with one-half of affected patients having three or more lesions, on the basis of autopsy evaluation.¹²⁴ Dissemination of *Candida* to other organs is frequently seen in addition to intracranial infection, and thus detection of lesions in other organs should prompt evaluation of the CNS as well. Outcomes of CNS *Candidiasis* are poor, with an associated 30% to 100% mortality rate.^{113,124,141,200}

In patients with intracranial devices, isolation of *Candida* from the CSF may represent colonization of the device or true intracranial infection. In a case series of 21 neurosurgical patients from whom *Candida* was isolated from CSF, nine patients with a single CSF culture did not receive antifungal therapy, and four patients underwent removal of the intracranial drain as the only intervention.¹¹³ These patients also had normal CSF parameters and were clinically asymptomatic. In contrast, 10 patients had multiple positive CSF cultures and were treated for *Candida* meningitis; most were symptomatic, with lethargy, fever, meningismus, focal neurologic signs, and neutrophilic pleocytosis. Isolation of *Candida* as a contaminant may occur even in the absence of an intracranial device. In a single-center case series of 23 infants and children from a single institution with fungi isolated from the CSF, six patients, the majority of whom did not have an intracranial device and five of whom had a negative CSF culture result on repeat sampling, were considered to have *Candida* as a contaminant and did not receive antifungal therapy, with a good outcome.¹⁰ Both studies highlight the importance of considering underlying medical conditions as well as the presence of other clinical signs and symptoms in the interpretation of *Candida* isolated from the CSF.

Ocular candidiasis. *Candida* may involve the eye during the course of candidemia and subsequent disseminated disease. Review of cohorts of children with candidemia who had eye examinations found that 3% to 8% of children had ocular dissemination.^{96,335} Endophthalmitis is thought to result from hematogenous seeding of the choroid and retina through the small vessels, with subsequent chorioretinitis manifesting as white chorioretinal lesions, or “fluff balls,” on the posterior fundus.²⁰ Vitritis is marked by extension of inflammation into the vitreous. Hypopyon, scleritis, retinal detachment, and optic nerve involvement may also occur. In patients who are able to report symptoms, “floaters” and blurred vision are the most common.²⁷⁴

Chronic Disseminated Candidiasis

Chronic disseminated candidiasis (CDC), sometimes referred to as hepatosplenic candidiasis when limited to the liver and spleen, is a distinct form of IC seen primarily in patients with leukemia and treatment-induced neutropenia. Involvement predominantly occurs in the liver, spleen, and occasionally other organs. *Candida* colonization of the gastrointestinal tract with subsequent dissemination through the portal venous circulation during periods of neutropenia is thought to be the predominant cause of this disease entity, especially when the process is limited to the liver and spleen. Prolonged neutropenia is the most cited risk factor for CDC; other reported risk factors include younger age and exposure to quinolone prophylaxis.^{198,262} Common symptoms of CDC include persistent fever and right upper quadrant

pain. The most common laboratory finding is a significantly elevated and persistent serum alkaline phosphatase level (median duration, 130 days); serum bilirubin and transaminase levels may exhibit brief elevation.²⁹⁵ CT has been shown to be more sensitive than ultrasound for the detection of hepatosplenic lesions, although MRI may be superior to both imaging modalities. Blood cultures are not often diagnostic, yielding positive results in less than 20% of patients with CDC. A biopsy for identification of *Candida* elements on histopathologic study or culture can confirm the diagnosis; however, the clinical, radiographic, and laboratory findings may be enough to direct therapy and avoid the need for an invasive diagnostic procedure.^{198,272} Clinical symptoms (i.e., fever), laboratory abnormalities (i.e., elevated alkaline phosphatase), and radiographic findings of CDC may manifest during neutropenia but often persist well after neutrophil recovery. The persistence of fever and lesions on radiographs has been hypothesized to represent a form of immune reconstitution syndrome against *Candida* species.²⁹⁵ Lesions are typically not apparent until neutrophil recovery, and they manifest on imaging as “wheel in wheel” target lesions, with biopsy showing histopathologic features of a central necrotic focus of yeast and filamentous forms with a surrounding rim of inflammatory cells.²⁹⁵

DIAGNOSIS

Culture

Isolation of *Candida* spp. from cultures of blood or other sterile sites is considered the gold standard of laboratory-based microbiologic confirmation of IC. However, the sensitivity of blood cultures is not ideal and varies depending on the clinical presentation of IC. The sensitivity of blood cultures for IC has been found to range from 60% to 83% in some studies and is even lower when considering when the specific clinical entity of CDC is considered.^{35,64,219} On the basis of studies evaluating the yield of blood culture systems inoculated with *Candida*, the sensitivity of commercially available blood culture media to detect candidemia varies by the type of culture media (aerobic, anaerobic, mycologic), inoculum size, and blood culture system. One study demonstrated that even when aerobic blood culture bottles were deliberately spiked with 10^5 *Candida* yeast cells, the yield was only 90%.¹³⁸ Depending on the blood culture system used, mycologic blood culture bottles may provide a slight advantage in the recovery of *Candida* because of the added benefit of a lysing agent to release viable phagocytosed fungal cells, the addition of nutrients essential to fungal growth, and antibiotics to suppress competitive bacterial growth in case of coinfection.¹³⁹ Time to positivity depends on inoculum size as well as specific *Candida* species.¹¹⁴ Using current automated blood culture systems, most *Candida* species have growth detected within approximately 24 to 36 hours, even at densities of 1 colony-forming unit (CFU)/mL, although *C. glabrata* has been shown to exhibit significantly longer time to positivity.^{114,139}

Although *Candida* spp. can grow on routine sheep's blood agar, use of selective fungal media such as Sabouraud dextrose agar or chromogenic *Candida* agar may enhance isolation of organisms from other types of body fluid and tissue specimens. However, despite the presence of visible yeast and pseudohyphae in the specimen, tissue culture results may still be negative. The yield of culture may also vary depending on the type of IC. For instance, tissue cultures in patients with hepatosplenic candidiasis have a particularly low yield. One study of 45 oncologic patients with hepatosplenic candidiasis who underwent biopsy reported that biopsy culture results were negative in 56.5%.²⁹⁵ Prior antifungal exposure, nonviable organisms in the specimen, and sampling error may contribute to negative culture results.

Histology

Histopathologic examination of tissue specimens may be an important alternative means to diagnose IC in suspected cases when culture results are negative, and they may be important in differentiating tissue invasion from surface colonization. Yeast, hyphae, and pseudohyphae may be visible on hematoxylin and eosin stain. Special fungal stains such as Gomori methenamine stain and periodic acid–Schiff should be used to enhance identification of *Candida* structures.

Antigen

In light of the poor sensitivity of blood cultures, the use of fungal biomarkers to establish a diagnosis of IC has been explored. One such biomarker is the (1→3) β -D glucan (BDG), which is a major cell wall component of most fungi (except *Mucorales* and *Cryptococcus* spp.), including *Candida*. Commercially available BDG assays harness the ability of BDG to activate a coagulation cascade in amoebocyte lysate from the horseshoe crab in what is called the Limulus test, by allowing measurement of this reaction through colorimetric or turbidimetric methods.¹⁴⁶ BDG is released into the blood and tissues during invasive fungal infection, and thus the availability of commercial assays represents an opportunity for indirect diagnosis of IC. Unfortunately, the sensitivity of the BDG assay for detecting any proven or probable invasive fungal infection has been low, ranging from 49% to 76.8% in multiple adult meta-analyses.^{79,146,177} Although these studies did not focus specifically on IC, the reported sensitivities do not appear substantially better than that of blood culture.

Furthermore, data on the use of BDG assays in children have been limited but call into question the applicability of adult data to pediatric populations. Mean serum BDG levels in healthy children have been found to be higher than that in adults (68 pg/mL vs. 48 pg/mL, respectively), thereby questioning whether the threshold of 80 pg/mL identified in the package insert for a positive test result is applicable to children.²⁸⁰ In addition, a prospective study evaluating *Candida* colonization and BDG serum values in children with leukemia demonstrated that 30% of colonized children exceeded the assay manufacturer positive cutoff values. None of the children developed evidence of invasive fungal infection, and the investigators postulated that absorption of BDG through the gut, or other sources of false-positive results, may have contributed to this result.²⁰⁵ Large prospective cohort studies are needed to assess the clinical utility of this test for diagnosing IC in the pediatric population.

A second biomarker, the mannan antigen and antimannan antibody assay, has been proposed as a tool for indirect diagnosis of IC. Mannan is an immunogenic polysaccharide that is a major component of the cell wall in *Candida* spp., and it can be found in serum during infection. Different assays have been developed to detect mannan antigen and antimannan antibodies, with enzyme-linked immunosorbent assays being the most frequently used in Europe.²⁰³ However, none of these assays have yet been approved by the US Food and Drug Administration for use in the United States. A meta-analysis of 14 studies evaluating the test characteristics of the mannan and antimannan antibody assays for proven and probable IC (on the basis of European Organization for Research and Treatment of Cancer/Invasive Fungal Infections Cooperative Group and National Institute of Allergy and Infectious Diseases Mycoses Study Group criteria) demonstrated a pooled sensitivity of 58% and specificity of 93% for mannan antigen. The antimannan antibody assay had a pooled sensitivity of 59% and specificity of 83%, whereas the pooled sensitivity of using combined mannan antigen and antimannan antibody assays was 83%, with a specificity of 86%.²⁰³ Significant heterogeneity of the studies in the meta-analysis was detected, however, and data have been extremely limited in the pediatric population. The increased sensitivity with the combination of mannan antigen and antimannan antibody assays make this an intriguing diagnostic tool, although the potential for false-positive results and the lack of pediatric specific data limit the ability to recommend these tests for routine clinical use in diagnosing IC.^{231,273} As with the BDG assay, prospective pediatric-specific studies are needed.

Molecular-Based Testing

Polymerase chain reaction (PCR)-based assays have also been evaluated in the diagnosis of IC. The ribosomal RNA gene cluster contains the 18 Svedburg (S), internal transcribed spacer (ITS) 1 and 2, 5.8S, and 28S regions and is a popular amplification target.¹⁷³ The presence of multiple copies of this ribosomal RNA cluster in fungal cells increases the sensitivity of PCR. Given that blood samples may contain only a small number of fungal cells (1 cell/mL),²³⁵ the ability of PCR-based assays to detect down to 0.22 cells/mL represents a potential advantage compared with conventional culture.¹⁷³ In addition, DNA derived from

both dead and living *Candida* cells can be amplified. Numerous DNA amplification methods have been developed including nested PCR, multiplex PCR, and real-time (RT) PCR platforms. Most studies have reported sensitivities near or equal to 100%, with a specificity greater than 90%.¹⁷³ In a prospective study comparing *Candida* RT-PCR, BDG assay, and blood cultures in the diagnosis of IC in 73 hospitalized adults, RT-PCR outperformed BDG for the detection of deep-seated candidiasis (89% vs. 53%; $P = .004$).²¹² Two studies examined the use of PCR to detect IC exclusively in the pediatric population. One study was conducted in neonatal and pediatric intensive care units, and the other was conducted in an oncologic population of patients presenting with fever and neutropenia. Both studies demonstrated high sensitivity.^{77,297} PCR-based assays for the detection of *Candida* are promising test modalities, but larger pediatric prospective studies and standardization of PCR techniques are needed before these techniques are incorporated into clinical practice.

Other Novel Diagnostic Approaches

The advancement of novel technologies provides the potential for more rapid and accurate identification of *Candida* to the species level. Matrix-assisted laser desorption/ionization–time of flight (MALDI-TOF) mass spectrometry uses a laser to irradiate a specimen resulting in charged ions of varying size that are then directed through a mass spectrometer. Particles are identified based on their time of flight, which depends on their mass-to-charge ratio. Comparison of MALDI-TOF mass spectrometry with biochemical identification by commercial assays revealed high agreement for species identification.²⁸⁹ The T2Candida assay (T2 Biosystems) combines the patient sample with species-specific magnetic nanoparticles. Clustering of the species with the magnetic nanoparticles can then be measured by T2-weighted MRI. An initial small study of pediatric patients with candidemia suggested that the assay is capable of accurately identifying *Candida* to the species level⁴⁸ directly from the blood specimen before culture. Both the MALDI-TOF and T2Candida technologies offer distinct benefit compared with conventional blood culture and subsequent biochemical testing because they can significantly reduce the time to organism identification.^{125,289} Whether these novel diagnostic tools will have improved overall sensitivity compared with blood culture is still not known.

ANTIFUNGAL PROPHYLAXIS AND TREATMENT

Prophylaxis

Consideration for antifungal prophylaxis has been given primarily to patients with the greatest risk for invasive fungal infection. Data from clinical trials on the efficacy of antifungal prophylaxis in the oncologic, liver transplant, intensive care unit, and surgical populations derive largely from studies in adults; antifungal prophylaxis in the neonatal population is a notable exception and is discussed later, in the neonatal candidiasis section.

Children undergoing chemotherapy for hematologic malignant diseases are at significantly high risk of developing invasive fungal infections, of which *Candida* spp. is most commonly identified. High-risk categories in this group can be refined further, with acute myeloid leukemia, relapsed acute lymphoblastic leukemia, allogeneic or autologous hematopoietic stem cell transplantation, and graft-versus-host disease associated with rates of invasive fungal infection ranging from 9% to 29%.⁸⁵ Severe aplastic anemia, although not an oncologic process, is also associated with a significant risk of invasive fungal infection because of bone marrow failure and prolonged neutropenia.³⁰³ Given the notable frequency of invasive fungal infection and the high mortality rates associated with IC in these patients,³⁰⁴ extrapolation from comparative data in adults with regard to the benefits of antifungal prophylaxis is reasonable. In a meta-analysis of 64 randomized controlled trials of antifungal prophylaxis in patients with cancer after chemotherapy or hematopoietic stem cell transplantation, antifungal prophylaxis led to a significant decrease in rates of all-cause mortality, fungal-related death, documented IC, and occurrence of any invasive fungal infection, compared with placebo, no treatment, or nonsystemically absorbed antifungal agents. The greatest benefit was seen in allogeneic and autologous hematopoietic stem cell transplant recipients.²⁵¹ Although

there is a dearth of randomized controlled trial data in children, more recent pediatric observational data in children with acute myeloid leukemia have suggested a mortality benefit of antifungal prophylaxis compared with no prophylaxis.⁹⁸

A detailed discussion of the comparative effectiveness of different antifungal prophylactic regimens is beyond the scope of this chapter. However, with regard to the type of antifungal prophylaxis, fluconazole is currently the most commonly recommended agent in high-risk children, given its proven survival benefit in adults, its low adverse effects, and its comparatively fewer common drug interactions compared with alternatives.^{85,271,301} In patients for whom broader antifungal coverage may be indicated, the extended-spectrum triazoles and the echinocandins are alternative options.^{85,302,304} Prophylaxis for high-risk patients is often administered for the duration of neutropenia in patients with prolonged neutropenia after a course of chemotherapy, for conditioning for hematopoietic stem cell transplantation, and in patients with severe graft-versus-host disease.²²⁶

Earlier studies in pediatric liver transplant recipients suggested a high rate of IC.^{51,115} More contemporary publications report a relatively low rate of IC in the post-liver transplant period and argue against the routine use of antifungal prophylaxis in this population.⁷⁶ On the basis of reports in adults, the Infectious Diseases Society of America currently recommends fluconazole or a lipid or liposomal formulation amphotericin B (LFAmB) as postoperative prophylaxis for 7 to 14 days for liver transplant recipients with at least two of the following risk factors: repeat transplantation, creatinine level greater than 2.0 mg/dL, choledochojunostomy, intraoperative use of more than 40 units of blood products, prolonged intraoperative time (>1 hour), and fungal colonization detected at least 2 days before and 3 days after transplantation.²²⁶ Prolonged operative time and the need for intensive care before transplantation have also been identified as risk factors for IC in children, and thus antifungal prophylaxis in these higher-risk patients may be warranted, similar to the adult recommendations.⁷⁶

Data on the benefit of antifungal prophylaxis for other pediatric organ transplant populations are limited. The adult expert consensus guidelines recommend fluconazole prophylaxis for small bowel transplant recipients for at least 2 weeks after transplantation.²²⁶ Pediatric small bowel transplant recipients appear to be at high risk of invasive fungal infection,¹⁰³ and thus extrapolation of the adult recommendation to children may be warranted.

The benefit of antifungal prophylaxis in pediatric intensive care unit patients remains unclear because more data are needed to identify prospectively those patients at highest risk for IC, as well as to define the benefit of targeted antifungal prophylaxis in this population. On the basis of data from adults, current guidelines suggest that antifungal prophylaxis may be warranted in intensive care units with very high rates of IC and in patients who are at highest risk (>10%) of IC.²²⁶

Treatment

The approach to treatment of superficial and IC should take into consideration the source of infection (e.g., endovascular, medical device associated), the site of involvement, *Candida* species and susceptibility profile, prior antifungal exposure, and the clinical status of the host, as well as drug-specific factors such as pharmacokinetic and pharmacodynamic properties and the potential for drug-drug interactions. This section focuses on the management of superficial and IC in the non-neonatal pediatric population and relies heavily on updated clinical practice guidelines issued by the Infectious Diseases Society of America.²²⁶ Detailed discussions of individual properties of antifungal agents are discussed in Chapter 240 and are not reviewed here.

The choice of antifungal therapy for *Candida* infections is influenced largely by the species causing the infection because certain *Candida* species exhibit characteristic antifungal susceptibility profiles. In general, the echinocandins are preferred for infection with *C. glabrata*, although transition to fluconazole or voriconazole is possible if susceptibility of the isolate is confirmed. Because the MIC values for echinocandins have been found to be higher for some *C. parapsilosis* isolates as a result of the presence of an intrinsic *FKS1* mutation encoding glucan synthase,³⁷ recommendations had been made to avoid echinocandins as first-line

therapy for this pathogen.²²⁶ However, the clinical significance of higher echinocandin MIC values in this species remains unclear. More recent adult epidemiologic data did not find a difference in outcomes between echinocandin and azole therapy among patients with *C. parapsilosis* infections,^{58,94} and thus the most recent IC guidelines no longer specifically recommend avoiding echinocandins for this pathogen.²²⁶

Although the general guidance provided in the previous paragraph can be helpful for empiric antifungal therapy choices, it is ideal to base decisions on sensitivity testing. Fortunately, the Clinical Laboratory and Science Institute (CLSI) provides clinical breakpoints for sensitive and resistant threshold testing for several *Candida* species. These breakpoints were updated in 2012 and are species specific⁶⁶ (Box 200.1). Routine performance of resistance testing for *Candida* spp. isolated from sterile site cultures should be considered as the standard of care to guide definitive therapeutic choices.

Dosing recommendations for antifungal agents in children continues to be a moving target as more pediatric specific pharmacokinetic data become available. Specific treatment choices with recommendations for dosing are provided in the following subsections for each clinical indication as a guide for the reader. However, when choosing a dose for a specific clinical case, the clinician should confer with a pharmacist or infectious disease specialist with expertise in antifungal dosing.

Superficial Candidiasis

Oropharyngeal candidiasis. Most patients with oropharyngeal candidiasis respond to topical antifungal therapy, although in patients with moderate to severe disease, systemic antifungal therapy may be required. In children with mild cases of oropharyngeal candidiasis, 4 to 6 mL of nystatin suspension (100,000 U/mL) may be administered four times daily as a swish-and-swallow medication. Effort should be made to prolong contact time with the oral mucosa as long as possible before swallowing because nystatin does not adhere well to the oral mucosa.¹³⁵ Clotrimazole, 10 mg troches administered five times daily, or one to two nystatin pastilles (200,000 U each) administered four times daily, can be used as alternatives. For infants, 100,000 to 200,000 units can be painted onto the affected areas four times daily. When applicable, cleaning of bottle nipples and pacifiers after each use should be attempted to reduce reintroduction of *Candida* through colonized surfaces. Treatment should be administered for 7 to 14 days.

For moderate to severe disease, systemic antifungal therapy is warranted. Oral fluconazole, 6 to 12 mg/kg (maximum, 100–200 mg/dose), may be administered for 7 to 14 days.²²² For fluconazole-refractory disease, itraconazole solution, 2.5 mg/kg twice daily, has been shown to be effective and safe in phase II clinical trials in children with cancer, liver transplantation, or HIV infection for the treatment of oropharyngeal candidiasis. Use of itraconazole in children is off-label because it has not been approved for use in children younger than 18 years of age.¹²¹ In children 2 to 11 years of age, or 12 to 14 years old and weighing less than 50 kg, voriconazole, 9 mg/kg (maximum, 350 mg) orally every 12 hours, may be administered, whereas children 12 to 14 years old and weighing 50 kg more, or children older than 14 years of age, should receive 200 mg orally every 12 hours as maintenance.^{121,106} In the event of treatment failure, amphotericin B deoxycholate (AmB-d), given as an oral 1-mL suspension four times daily, may be tried. Intravenous therapies such as echinocandins and amphotericin B products should be considered as last resorts in children with persistent disease. In an otherwise healthy child, long-term suppressive therapy is often unnecessary. However, in children presenting with persistent or recurrent episodes, an underlying primary, acquired, or iatrogenic immune defect should be investigated. Long-term suppressive therapy can be considered in children with an immunodeficiency predisposing to persistent or recurrent oropharyngeal candidiasis. In such settings fluconazole three times weekly is considered the regimen of choice.²²⁶

Esophageal candidiasis. The treatment of esophageal candidiasis requires systemic antifungal therapy. Oral fluconazole, at 6 to 12 mg/kg daily (or 200–400 mg daily) for 14 to 21 days, is recommended.²²² For fluconazole-refractory disease, itraconazole, voriconazole, and caspofungin are suitable alternatives (see earlier for pediatric dosing). As in oropharyngeal candidiasis, long-term suppressive therapy with fluconazole three times weekly may be administered.²²⁶

BOX 200.1 Neonatal Cutaneous Candidiasis Definition

Definition: Extensive *Candida* rash covering ≥ 2 affected areas from A and/or B

Affected Areas

- A. Skin
 - Chest
 - Abdomen
 - Back
 - Extremity
 - Groin or perineal area
 - Neck
 - Face or scalp
- B. Umbilical cord and placenta
 - White plaques on umbilical cord
 - Placenta with yeast invasion

Timing

CCC: Presenting in the first 48 h of life; usually present at birth

CC: Presenting after 2–7 days of life

Skin Rash

Macular-papular
Scaly, erythematous
Dry flaking
Desquamating
Burn-like erythematous

Presentation

Extensive

- Covering ≥ 2 affected areas (see below)
- Covering 1 affected area (see below); umbilical plaques or placental pathologic features (silver or H&E) would count as 1 affected area

Evaluation

CCC: Skin rash sites, placental and/or cord culture, and pathologic examination with silver stain for yeast blood culture and CSF (unless rash over lumbar area; if so, treat empirically for meningitis)

CC: Skin rash sites, blood, urine, CSF (unless rash over lumbar area; if so, treat empirically for meningitis)

Diagnosis

One or more of the following:

- Surface culture isolating *Candida* species
- Placental or cord identification (culture or silver stain) of yeast or *Candida* species for CCC
- Positive blood, urine, CSF cultures for *Candida* species

Treatment

Preterm infants (<37 weeks' gestation): 14-day course of IV antifungal therapy

Full-term infants: IV antifungal therapy pending culture results

CC, Cutaneous candidiasis; CCC, congenital cutaneous candidiasis; CSF, cerebrospinal fluid; H&E, hematoxylin and eosin; IV, intravenous.

Vulvovaginal candidiasis. The approach to the treatment of vulvovaginal candidiasis varies depending on the presence of complicated vulvovaginal disease (severe disease, four or more episodes of symptomatic vulvovaginal candidiasis in 1 year, non-*C. albicans* infection, or abnormal host).⁸² For uncomplicated cases topical therapies are effective, and no data have revealed the superiority of any topical regimen.^{248,282} In a meta-analysis of 19 randomized, controlled trials oral and topical antifungal regimens had similar effectiveness.²¹⁷ Topical therapies are often administered for 3 days. Uncomplicated vulvovaginal candidiasis

can also be effectively treated with a single oral dose of fluconazole. In patients found to have vulvovaginal candidiasis from a fluconazole-resistant isolate, topical nystatin has been shown to be effective.⁹¹ Complicated vulvovaginal candidiasis often requires extended therapy either with 1 week of a topical agent or three doses of oral fluconazole each separated by 3 days.² The management of recurrent vulvovaginal candidiasis was studied in a randomized controlled trial. All patients were started on three doses of fluconazole every 3 days and then randomized to once a week fluconazole for 6 months versus placebo. Patients in the former group had 90% response rate versus 36% in the placebo arm.²⁸⁴ These data support a prolonged maintenance therapy phase for patients with recurrent disease.

Cutaneous candidiasis. Because moist, macerated skin promotes the development of cutaneous candidiasis, it is important to keep affected areas dry as much as possible; antifungal therapy alone usually does not produce a cure. For candidal diaper dermatitis, frequent diaper changes should be performed. Topical antifungal therapy with nystatin or azoles may be applied twice daily and continued until symptoms resolve.

Invasive Candidiasis

Candidemia. All pediatric patients with candidemia require systemic antifungal therapy. The adult guidelines support an echinocandin as the preferred therapy for candidemia on the basis of improved efficacy in adult trials likely related to the fungicidal activity against *Candida*.²²⁶ Data comparing the effectiveness of antifungal therapies in children are limited. Retrospective data suggest similar outcomes among children treated with fungicidal and fungistatic agents.³¹⁶ However, until more definitive pediatric data are available, clinicians should defer to the adult guidelines. Certainly, for neutropenic patients, patients who are critically ill, or those with recent azole exposure, an echinocandin should be considered first-line therapy. LFAmB (3–5 mg/kg daily) may be given as an alternative option in these clinical situations. In children in clinically stable condition who do not meet any of the aforementioned criteria, fluconazole therapy may be given as a first-line agent at 12 mg/kg intravenously (IV) daily. Step-down therapy to fluconazole is recommended for patients with susceptible isolates, whereas voriconazole may be offered as step-down oral therapy for candidemia resulting from *C. krusei* or susceptible *C. glabrata*.²²⁶ In children 2 to 11 years, or 12 to 14 years and weighing less than 50 kg, voriconazole may be given as a 9 mg/kg loading dose IV every 12 hours on day 1, followed by 8 mg/kg IV every 12 hours as maintenance. Oral dosing may be given as 9 mg/kg (maximum, 350 mg) every 12 hours. In children 12 to 14 years and weighing 50 kg or more, or children more than 14 years old, dosing should be as in adults and may be given as a 6 mg/kg loading dose IV every 12 hours on day 1, followed by 4 mg/kg IV every 12 hours as maintenance, whereas oral dosing may be given as 200 mg every 12 hours as maintenance.^{121,106}

A dilated funduscopic examination should be performed in all patients with candidemia after initiation of antifungal therapy, and routine blood cultures should be performed to document clearance of *Candida* from the bloodstream. The eye examination should be reserved until after documented clearance of candidemia. In patients without evidence of disseminated disease, antifungal therapy should continue for 14 days from symptom resolution and documented bloodstream clearance of *Candida*. In patients with candidemia in the setting of neutropenia, therapy is often continued until neutrophil count recovery.

Current guidelines recommend that central venous catheters in patients with candidemia should be removed when possible because data from most observational studies in children and adults have shown fewer rates of complications, reduced mortality rates, and more rapid rates of response to antifungal therapy.^{8,75,101,229,249} This recommendation comes with acknowledgment of potential residual confounding in these observational studies, specifically the possibility that patients whose central venous catheters were retained had significantly more severe illness compared with patients whose catheters were removed, thus precluding catheter removal.²¹⁶ Nonetheless, the consistent and cumulative observational data support line removal as early as possible.

Candidemia in the neutropenic patient is further complicated by the issue that the source of infection may be the gastrointestinal tract,

and thus the significance of catheter removal when candidemia is documented is less clear. In a single-center study of 404 patients with cancer and central venous catheters in place at the time of candidemia, the investigators attempted to differentiate candidemia associated with the central venous catheter from candidemia associated with a non-catheter source and to define the benefit of timing of catheter removal on resolution of candidemia-associated symptoms and blood culture sterilization. In patients with evidence of catheter-associated candidemia, catheter removal up to 72 hours from first positive blood culture result was found to be significantly associated with improved response rates compared with removal after more than 72 hours, whereas patients with candidemia resulting from an alternate or undefined source did not have a statistically significant improvement in response rates with early catheter removal.²⁴² Other data have shown mixed results in support of early removal of catheters in candidemic patients with cancer.^{186,315} Although the data are not definitive, central catheter removal should still be strongly considered when feasible in children with neutropenia.

Endovascular candidiasis. Data informing evidence-based practice for management of *Candida* endocarditis are limited, but endocarditis and IC guidelines support a multipronged approach including antifungal therapy and surgical intervention.^{22,226} Fungicidal regimens are preferred for *Candida* endocarditis, and most experience in the literature involves the use of AmB-d with or without flucytosine. LFAmB is associated with less toxicity and permits higher dosages; thus LFAmB (3–5 mg/kg IV daily), with or without flucytosine (100–150 mg/kg per day in four divided doses enterally), is recommended for the treatment of native valve and prosthetic valve *Candida* endocarditis in the non-neonatal population. Echinocandins are considered a second-line option. In a small observational study, outcomes of patients receiving amphotericin B–based therapy versus echinocandin-based therapy were similar.¹¹ Data from case reports, case series, and a meta-analysis^{30,290} suggest that surgery is an important adjunct to antifungal therapy, and these data serve as the basis for recommendation that patients with *Candida* endocarditis undergo surgical resection of the infectious process. The duration of antifungal therapy is recommended to be at least 6 weeks from surgical intervention for native valve endocarditis. In patients unable to have surgical resection or in those with initial prosthetic valve endocarditis, a transition to long-term suppressive therapy with an azole agent after completion of initial therapy is recommended.^{16,226}

Cardiac candidiasis. Pericarditis and myocarditis caused by *Candida* spp. are both rare clinical entities, and thus data are limited to guide management. A report documented the successful use of amphotericin B for *Candida* pericarditis,²⁶⁸ and the known lower toxicity profile seen with LFAmB suggests that pericarditis can be treated with LFAmB. An echinocandin or azole (assuming a susceptible isolate) is a logical alternative. Treatment should be continued for several months, in combination with either a pericardial window or pericardiectomy, because this appears to be the best approach for achieving cure.²⁶⁸ Step-down therapy to fluconazole can be considered in patients in clinically stable condition who have shown an initial response to an amphotericin product or echinocandin.

Peritoneal candidiasis. As noted earlier, peritoneal candidiasis can manifest in various clinical forms, but in children it is most often related to presence of a peritoneal catheter. Most experts agree that peritoneal catheters should be removed in patients with peritoneal candidiasis; the basis of this recommendation is the high rates of treatment failure seen in case series of patients with retained catheters, as well as the known challenges involved in treating biofilm present on the device.^{52,166,207} Recommendations call for prompt (<24 hours) removal of the peritoneal catheter on diagnosis of fungal peritonitis.¹⁸³ This recommendation is supported by observational data showing reduced mortality rates in adults with early catheter removal compared with delayed removal.⁵³ Peritoneal candidiasis requires systemic administration of an antifungal agent. No comparative data exist on the ideal antifungal agent, and data on the ability of available antifungal agents to reach the peritoneum are limited. Some reports suggest that fluconazole may be more able to penetrate the peritoneum than amphotericin B products.^{199,42} Fluconazole may also be given intraperitoneally as a 75 mg/L concentration added daily to the dialysate after a systemic loading dose.²⁰⁶ Intraperitoneal

AmB-d has been associated with severe peritoneal irritation, as well as fibrosis and membrane loss, and it should be avoided.⁹ The role of echinocandins in fungal peritonitis is not yet well defined, and some data suggest that the fungicidal activity of the echinocandins may be reduced by PD fluid.³⁰⁰

Candidiasis of the urinary tract. No treatment is recommended for patients with asymptomatic candiduria. In patients with an indwelling catheter, removal of the device may be adequate to resolve the candiduria without antifungal therapy. Fluconazole is highly water soluble, is primarily excreted into the urine as active drug, and expected urinary concentrations are more than 10-fold those in serum, thereby exceeding the MIC even for susceptible dose-dependent *Candida* species.¹⁰² Thus fluconazole is considered the drug of choice for both cystitis and pyelonephritis. LFAmB should not be used to treat *Candida* UTIs because of the low drug levels achieved in the renal parenchyma and urine. Although voriconazole was shown in an animal model of renal parenchymal candidiasis to be superior to AmB-d or fluconazole, urine voriconazole levels are low, with less than 5% of the active drug excreted, which limits the drug's utility in the treatment of UTIs. Similarly, the echinocandins have been shown in experimental models to clear renal parenchymal infections in the setting of disseminated candidiasis, but very little active drug is excreted in the urine, and clinical experience with treatment of UTIs is limited. For fluconazole-resistance organisms, AmB-d or oral flucytosine is an alternative. Continuous bladder irrigation with AmB-d has also been used to treat *Candida* cystitis, although relapse rates after local bladder irrigation are high.¹⁰²

Mycetomas (fungus balls) in the urinary collecting system may not respond to medical management alone, and thus surgical intervention may be necessary for source control. Surgical procedures include options such as endoscopic removal or instillation of AmB-d into the mycetoma through a nephrostomy tube. Pediatric data to guide decisions on when to invoke a surgical intervention for mycetoma or what intervention is ideal are limited.

Osteoarticular candidiasis. The management of osteoarticular *Candida* infections is challenging because no pediatric-specific comparative data are available to guide antifungal therapy choices. Furthermore, regardless of the therapeutic option, the rate of disease relapse is high.^{110,278} Therapeutic options include fluconazole, an echinocandin, or LFAmB. Adult guidelines favor fluconazole as primary therapy and offer an alternative regimen that includes either an echinocandin or LFAmB for a 2-week induction period with step-down therapy to fluconazole. Regardless of the therapeutic choice, a total duration of 6 to 12 months is recommended.²²⁶ Fluconazole 12 mg/kg daily, or intravenous LFAmB, at 3 to 5 mg/kg daily for at least 2 weeks, followed by step-down therapy to fluconazole, at 6 mg/kg daily for 6 to 12 months, is currently recommended. Echinocandins may be a suitable alternative to upfront parenteral LFAmB administration. Adjunctive surgical debridement may be beneficial in select cases.

For septic arthritis, a minimum of 6 weeks of fluconazole or LFAmB or an echinocandin for at least 2 weeks followed by fluconazole is recommended. Adequate surgical drainage is a crucial aspect of the management of non-neonatal *Candida* arthritis, and it should be performed in all cases.²²⁶

Central nervous system candidiasis. Most experience in the literature regarding the treatment of *Candida* CNS infections has been with AmB-d, with or without flucytosine.^{10,113} Liposomal formulation Amphotericin B has been preferred because of its lower toxicity profile and known tissue penetration in the brain. The combination of liposomal formulation Amphotericin B and flucytosine has demonstrated synergism in vitro, and flucytosine achieves excellent CSF concentrations, thus making combination therapy attractive. Limited experience with the echinocandins has revealed both treatment successes and failures, in addition to breakthrough CNS infections after therapy for candidemia. The echinocandins have poor CSF penetration, with low levels compared with serum.⁷⁸ As a result, this antifungal class is not recommended for CNS candidiasis. Current recommendations for treatment of *Candida* CNS infection are to administer intravenous LFAmB 3 to 5 mg/kg daily with or without flucytosine (100–150 mg/kg per day in four divided doses enterally) for the initial several weeks of treatment, followed by step-down therapy to fluconazole (12 mg/kg daily) once a treatment response to LFAmB has been established. The ultimate duration of

therapy is not known, but antifungal therapy should continue until all clinical and radiographic evidence of disease has resolved. Removal of infected intracranial devices is strongly recommended.²²⁶

Ocular candidiasis. No prospective studies exist for the treatment of *Candida* endophthalmitis, but current guidance is contingent on presence or absence of vitritis. All cases of *Candida* endophthalmitis require systemic antifungal therapy. Options for systemic therapy include fluconazole, voriconazole, or LFAmB with or without flucytosine.²²⁶ No comparative data exist to establish the superiority of any of these options for ocular disease. However, given that fluconazole and voriconazole achieve reasonable posterior segment eye concentrations, some investigators favor these agents as first-line options over AFAmB.²⁵⁰ Patients with vitritis or macular involvement of the retina are recommended to have intravitreal therapy with either voriconazole or AmB-d. In severe cases of vitritis, vitrectomy may help reduce the burden of infection. The optimal duration of antifungal therapy is not determined, but therapy should be continued until clinical evidence of infection has resolved. At minimum therapy should be for at least 4 to 6 weeks.²²⁶

Chronic disseminated candidiasis. Treatment recommendations for CDC are made on the basis of case reports and series; however, most clinical experience has been with AmB-d, LFAmB, and fluconazole. In clinically stable patients, fluconazole is recommended. Echinocandins or an amphotericin B product can be used to treat acutely ill patients or patients nonresponsive to fluconazole, either as a 1- to 2-week induction period before fluconazole step-down therapy or as single therapy. The duration of therapy for CDC is variable, depending on the clinical situation and the patient's response to treatment, but typically it is prolonged, with a median duration of more than 3 to 5 months.¹⁹⁸ Most experts recommend that antifungal therapy continue until all lesions resolve or calcify.²²⁶ Continuation of chemotherapy has been shown to be safe in these patients, and stem cell transplantation may be performed if indicated in patients whose disease is controlled.^{40,324} The prolonged fever and persistence of lesions in patients with this chronic entity have been hypothesized to be secondary to a type of immune reconstitution inflammatory syndrome. As such in patients with persistent fevers, adjuvant low-dose corticosteroid therapy in addition to antifungal therapy has been proposed. This therapeutic approach has been shown to result in symptom resolution.^{56,179} This intervention can be considered in select cases of persistent symptoms, but more data are needed for routine recommendation of corticosteroids.

NEONATAL CANDIDIASIS

Epidemiology

IC in neonatal intensive care units (NICUs) remains a serious health problem because it is associated with substantial morbidity and mortality. Strategies for prevention and management of IC are paramount for improving outcomes for neonates.^{30,31,153,292,338} The incidence of candidiasis had increased in the NICU as advances in medical therapy allowed for increased survival of extremely low-birth-weight (ELBW) and low-gestational-age premature infants between the 1980s and 1990s and then remained stable until 2001, when a decreased incidence was observed.^{5,62,107,171} More recent evidence has shown that the incidence of candidiasis is decreasing, from 3.6 to 1.4 per 1000 NICU admissions between 1997 and 2010.⁵ The decrease in candidiasis may be related to the increased use of fluconazole prophylaxis at high-incidence centers, decreased use of broad-spectrum antibiotics, and improved infection control practices.

C. albicans and *C. parapsilosis* infections account for 80% to 90% of neonatal IC in centers not using antifungal prophylaxis.³¹ Centers using fluconazole prophylaxis are more likely to observe infections caused by non-*albicans* *Candida* species. Less common *Candida* species include *C. glabrata* and *C. tropicalis*, and a few infections are caused by *C. lusitanae*, *C. guilliermondii*, or *C. dubliniensis*.

IC in the infant include congenital cutaneous candidiasis (CCC) and late-onset cutaneous candidiasis, candidemia, UTIs, meningitis, peritonitis, and infection of other sterile sites (bone and joint infections).

Prematurity is the predominant factor predisposing hospitalized infants to IC. The immune system of the premature infant has defects in chemotaxis, cytokine and antibody production, and phagocytosis.^{55,182}

FIG. 200.1 Invasive candidiasis by gestational age and birth weight in infants weighing less than 1000 g. Invasive candidiasis: candidemia, urinary tract infection, meningitis, or peritonitis in infants weighing <1000 g at birth who were not receiving antifungal prophylaxis. Gestational age has a linear relationship with invasive candidiasis that aids in defining the highest-risk patients. (Data from 137 infections in 1515 infants weighing less than 1000 g from 19 centers of the National Institute of Child Health and Human Development Neonatal Research Network.)

In addition, invasive medical devices such as central venous catheters and endotracheal tubes compromise already underdeveloped skin and place the premature infant at an especially high risk for IC.

There is significant variation in the incidence of IC by NICU. This variation by NICU has been attributed to differences in patients' demographics, use of antifungal prophylaxis, surgical population, resuscitation of extremely preterm infants, feeding protocols, and antibiotic prescribing practices. The incidence has been reported to range between 3% and more than 23% among NICUs in infants weighing less than 1000 g.^{31,107,71} Among 128 US NICUs using National Nosocomial Infections Surveillance (NNIS) system data from 1995 to 2004 ($n = 130,523$ infants),¹⁰⁷ the median incidence of candidemia was 7% for infants weighing less than 1000 g, and 25% of NICUs had rates of 13.5% or higher. The incidence of candidemia for infants with birth weights of 1001 to 1500 g was 1.3%, for weights of 1501 to 2500 g it was 0.4%, and for those weighing more than 2501 g it was 0.3%. The highest incidence of IC occurs in the most extremely preterm infants and is greater than 20% for infants at less than 25 weeks of gestation (Fig. 200.1).³¹

Infants with complex congenital anomalies or those requiring surgical procedures are also at high risk of IC. Feja and colleagues⁹³ found that candidemia was increased in patients with gastrointestinal disease (OR, 4.57; 95% CI, 1.62–12.92). Gastrointestinal disease was defined in their study as tracheoesophageal fistula, gastroschisis, omphalocele, Hirschsprung disease, intestinal atresias, or episodes of necrotizing enterocolitis (NEC). Candidemia accounts for 9% of BSIs in patients with congenital heart disease cared for in NICUs in the first 4 months of life.¹² *Candida* BSI occurred in 6.3 per 1000 admissions and had an overall mortality rate of 21%. *Candida* species are the second most common causes of infection in infants on extracorporeal membrane oxygenation and are responsible for 10% of infections.³⁹

Risk Factors

Given that neonatal candidiasis can be fatal among premature infants, an understanding of the risk factors that lead to infection within this high-risk group is critical. Conditions that facilitate fungal colonization and proliferation and increase the risk for invasive infection include gastrointestinal dysmotility or ileus, antibiotics, acid inhibition, steroids, and the patient's immune system immaturity. Several risk factors have been identified, with gestational age having the strongest effect. This correlates with the degree of the underdeveloped immune system, skin, and gastrointestinal tract in these infants.

The immature lymphocyte and antibody system predisposes premature infants to skin and mucosal fungal colonization, whereas deficient innate host defense mechanisms predispose them to dissemination and overwhelming infection. With compromise of the barrier defense system, IC may result from deficient neutrophil number and function. Neutrophils provide the major role in antifungal defense, ingesting and killing *Candida* in a process requiring production of oxygen metabolites,

Pathogenesis. Invasive *Candida* Infections

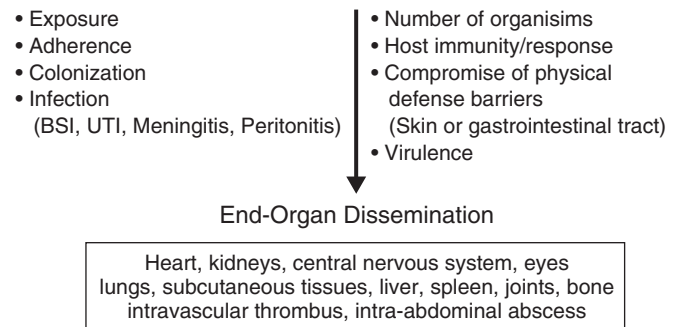

FIG. 200.2 Pathogenesis of invasive candidiasis. BSI, Bloodstream infection; UTI, urinary tract infection.

antibodies, and cytokines and activation of the C3 complement component, all of which are decreased in premature infants compared with term infants and adults. Also deficient are neutrophil granules and cytokines that play a critical role in the lysis of *Candida* hyphae and pseudohyphae, which are too large to be engulfed by phagocytosis. Macrophages have impaired adherence, phagocytosis, and oxidative killing in preterm infants, thus affecting their ability to contain fungal colonization and infection. In addition to cell-mediated defenses, cytokines contribute to innate immunity against fungal infection through enhancement of cell-mediated fungicidal activity. Pulmonary host defense is primarily through alveolar macrophages, cilia and mucus, and surfactant, all of which are deficient in preterm infants.

Risk factors for *Candida* colonization and sepsis are similar.^{260,261} Colonization of the skin, mucosal membranes, and vascular catheters commonly precedes infection. Biofilm formation on catheters inhibits the host's defense mechanisms and the penetration of antifungal agents.

Infants may be colonized through maternal transmission or acquire colonization during their admission in the NICU. Colonization in ELBW (<1000 g at birth) infants has been reported to be as high as 46% in the first 28 days of life.¹⁶⁶ Fungal colonization of the skin, respiratory tract, or gastrointestinal tract occurs in 10% of full-term infants compared with 27% to 62% of very low-birth-weight (VLBW; <1500 g at birth) infants in the first weeks of life.¹⁵⁵ Fungal colonization and subsequent infection depend on exposure, size of inoculum, host susceptibility, and properties of the pathogen (Fig. 200.2).

In a multicenter trial examining fungal colonization in six NICUs, *Candida* species were isolated on the hands of 29% (859 of 2989) of health care workers.²⁶¹ Although *C. albicans* was the more common fungal isolate in all NICU patients (14% vs. 7%), *C. parapsilosis* was

the most common species isolated from the hands of NICU staff. *C. parapsilosis* was isolated from 19% (similar to a single-center incidence of 20%) and *C. albicans* from 5% of the cultures from health care personnel ($P < .001$). *C. lusitanae* (2%), *C. guilliermondii* (1%), *C. tropicalis* (<1%), and *C. glabrata* (<1%) were also recovered from hand cultures. Increased handling required by sicker preterm infants increases the risk of acquiring fungal colonization from health care workers' hands, contaminated infusates, catheters, or catheter-related devices because there are an average of 32 touches of infants directly during a 12-hour shift.^{67,261}

The skin and gastrointestinal tract are the most common sites for *Candida* colonization.^{21,157} Colonization is inversely proportional to gestational age, and fungal colonization occurs on the skin and gastrointestinal tract before the respiratory tract. *Candida* species produce proteases that may be lytic for the thin keratin layer produced by the immature stratum corneum and phospholipases against lipid membranes that both may facilitate epithelial invasion.^{88,155} Increased transepidermal water loss from preterm skin creates a moist environment that facilitates fungal colonization and growth. Because of the increased permeability of the preterm skin, substrates such as glucose may diffuse to the epithelial surface and facilitate *Candida* growth. *Candida* may alter its surface structure in the presence of high glucose, thus increasing its adherence and proliferative properties. Skin maturation occurs by 2 weeks of life in the extreme preterm infant, after which new fungal skin colonization occurs less frequently.

The microflora of the gastrointestinal tract plays an important role in fungal colonization and infection. Buccal candidal adherence is increased in preterm compared with term infants and facilitates colonization.⁷² A normal bacterial flora inhibits *Candida* growth by competing for both adhesion sites and nutrients.^{133,162} In a study of athymic mice given an oral challenge with *Candida*, fungal colonization was attenuated in mice with a normal gut flora compared with those with a germ-free microflora.¹³³ This finding highlights the fact that the intestinal microflora may be as important as an intact immune system in preventing fungal colonization.

Although colonization of skin and gastrointestinal tract is more common and precedes respiratory tract colonization, endotracheal colonization has a higher risk for infection.¹⁵⁹ Rowen and associates²⁵⁶ demonstrated that with endotracheal fungal colonization, candidemia was 15.4 times more likely to occur compared with infants without any fungal colonization. Controlling for fungal colonization at other sites, endotracheal colonization alone increased the risk for fungal sepsis (risk ratio, 5.9; 95% CI, 1.34–26).

Use of broad-spectrum antibiotics enhance *Candida* colonization by destroying competing bacterial flora.¹⁵⁵ In a cohort of more than 6000 infants, cephalosporin or carbapenem use in the previous 7 days was associated with candidiasis.²⁷ Histamine-2 (H_2)-blocking and proton pump inhibiting agents have been shown to increase *Candida* overgrowth in the gastrointestinal tract of adults,¹¹⁷ and their use is associated with candidiasis in infants.²⁶²

The extremely preterm infant has the unique combination of being immunocompromised (including an immature skin and gastrointestinal tract), requiring prolonged intensive care (parenteral nutrition, mechanical ventilation, central venous access), being exposed to medications that promote fungal growth (H_2 -blocking agents, proton pump inhibiting agents, postnatal corticosteroids, and broad-spectrum antibiotics), and having an increased rate of gastrointestinal dysmotility and disease (NEC and focal bowel perforation).^{31,93,260} Infants with complicated gastrointestinal diseases such as gastroschisis or NEC have combined risk factors of prolonged ileus, central venous access, parenteral nutrition, surgery, and exposure to prolonged or broad-spectrum antibiotics.⁹³

Clinical Manifestations

Congenital Cutaneous Candidiasis

CCC is an uncommon clinical condition in which the infant at birth has a diffusely erythematous papular rash (Fig. 200.3; see also Box 200.1).⁷⁴ CCC is caused by an ascending infection into the uterus before birth. The papular rash becomes pustular, followed by the development of vesicles and bullae. The rash may also develop as bright red, burn-like dermatitis. The skin involvement covers one or more of

the following areas: face or scalp, chest, abdomen, perineal area, one or more extremities, and back. These lesions occasionally lead to desquamation. ELBW infants with CCC are at greater risk of developing dissemination to blood, urine, or CSF (66%) compared with 33% in those 1000- to 2500-g or term infants (11%). For this reason, all these infants should be treated with systemic antifungal therapy.

In a study examining the pathogenesis and pathology of these infections, skin biopsies demonstrated invasion into the epidermis with an inflammatory process ranging from dermal invasion and granuloma formation to focal necrosis and hemorrhage.²⁵⁷ These data from biopsies give insight into the invasive nature of cutaneous involvement and demonstrate that these infections are invasive and need prompt systemic antifungal therapy. Routine aerobic skin culture will isolate the *Candida* species and cause the cutaneous manifestations (skin biopsies are not needed.) By culturing for both fungal and bacterial organisms, the source of infection can be determined promptly and treatment started in a timely fashion. Differential diagnosis includes staphylococci, other bacteria, and other fungal skin infections. Pathologic examination with fungal staining of the umbilical cord and placenta can also aid in diagnosis.

Neonatal Candidemia

BSI with fungal species manifests with clinical signs and symptoms similar to those of bacterial sepsis. The following signs and symptoms occur, in order of their prevalence with candidemia⁹²: thrombocytopenia of less than 100,000/ μ L (84%), immature-to-total neutrophil ratio of 0.2 or greater (77%), increase in apnea or bradycardia (63%), oxygen requirement (56%), assisted ventilation (52%), lethargy or hypotonia (39%), gastrointestinal symptoms (e.g., gastric aspirates, distention, bloody stools) (30%), hypotension (15%), hyperglycemia (13%), elevated white blood cell count greater than 20,000/ μ L (12%), metabolic acidosis (11%), and absolute neutrophil count lower than 1500/ μ L (3%). Most importantly, candidemia can be associated with disseminated disease. Evaluation of cardiac, renal, and ophthalmologic systems and the CNS is warranted.

Neonatal Urinary Tract Infection

Among infants with IC, up to 40% may have kidney involvement.³¹ *Candida* infections of the renal system include cases of isolated candiduria, fungal debris within the renal collecting system, and renal parenchymal involvement.¹⁴⁷ If the urine culture result is positive for *Candida*, renal ultrasonography should be performed to assess for disease in the collecting system. Candiduria develops in approximately 2.4% of VLBW infants and in up to 6% of ELBW infants.^{31,157} Studies have demonstrated similar mortality rates in infants with *Candida* UTIs alone (26%) compared with *Candida* BSIs (28%) in ELBW infants.³¹

Neonatal Meningoencephalitis

Among infants, meningitis is found in approximately 15% of cases of candidemia, much higher than the incidence of meningitis observed in adults with candidemia.²⁸ This fact has important implications for diagnostic evaluation and therapeutic approaches because clinicians cannot assume that the CNS is not involved in otherwise seemingly straightforward candidemia. Candidiasis of the CNS is accurately described as meningoencephalitis because infection often results in granulomas, parenchymal abscesses, and vasculitis. Importantly, fungal abscesses of the CNS have been reported to be microscopic and not readily detectable by ultrasonography. Furthermore, CSF parameters in the presence of CNS infection may be normal.^{108,155} In a study of 46 ELBW patients with fungal sepsis and/or meningoencephalitis, only six of 13 patients with fungal CNS abscesses (detected by ultrasound, CT scan, or autopsy) had abnormal results on lumbar puncture.¹⁰⁸ Studies have found an association between invasive fungal infection and periventricular leukomalacia in preterm infants, possibly related to release of cytokines that may damage the periventricular white matter.¹⁰⁸

Neonatal Endocarditis and Infected Vascular Thrombi

Candida endocarditis has been reported in 5.5% to 15.2% of cases of fungal sepsis, with equal prevalence for *C. albicans* and *C. parapsilosis*.

FIG. 200.3 Various presentations of congenital cutaneous candidiasis. (A) Macular papular rash. (B) Dry, flaky rash. (C) Dry, cracking scaly rash. (D) White plaques of the umbilical cord.

Candida endocarditis may be associated with higher mortality rates than candidemia alone.^{55,213} Central vascular catheters place infants at increased risk for endocarditis and infected vascular thrombi. As discussed previously they can cause local trauma to valvular, endocardial, or endothelial tissue creating a nidus for thrombus and infection.

Neonatal Endophthalmitis and Retinopathy of Prematurity

The incidence of retinal endophthalmitis with candidemia has decreased over the years, likely because of more rapid diagnosis, treatment, and surveillance of systemic candidemia. In a retrospective study from 1989 to 1999, 6% (four of 67) of preterm infants with fungal sepsis who had indirect ophthalmoscopy examination had endophthalmitis.²¹³

Even in absence of visible retinal abscesses or chorioretinitis, some epidemiologic evidence suggests that *Candida* sepsis may predispose preterm infants to severe retinopathy of prematurity (ROP). In a study of ELBW infants, threshold ROP developed in 33% (19 of 58) of infants with a history of candidemia compared with 10% (39 of 391) without candidemia, but this was not statistically significant when controlling for gestational age.¹⁴⁸ Conversely, Noyola and colleagues,²¹⁴ in a case-control study of VLBW infants and infants at less than 28 weeks of gestation, found that 52% (24 of 46) of infants with candidemia developed threshold ROP compared with 24% (11 of 46) of controls without candidemia ($P = .008$). Although the data on an association between fungal sepsis and ROP are conflicting, early and frequent screening for retinal disease is recommended in preterm infants with candidemia.

Neonatal Candida End-Organ Dissemination

At the time IC is clinically apparent, the organisms have often disseminated from the blood, urine, or CSF to adhere and proliferate in body fluids, tissues, and organs. *Candida* species can cause endocarditis, endophthalmitis, dermatitis, peritonitis, osteomyelitis, and septic arthritis,

and abscesses may form in the CNS, kidneys, liver, spleen, skin, bowel, and peritoneum (Fig. 200.4). A review of 21 manuscripts found the following median prevalence rates for end organ involvement in the setting of IC in infants: endophthalmitis, 3% (interquartile range, 0–17%); endocarditis, 5% (0–13); and hepatosplenic abscesses, 1% (0–3%).²⁸ Dissemination may be higher in the lower-birth-weight infant.

Noyola and colleagues²¹³ and Chapman and associates⁵⁵ found that infants with candidemia for more than 5 and 7 days, respectively, were more likely to demonstrate ophthalmologic, renal, or cardiac abnormalities than infants with a shorter duration of candidemia. When amphotericin B was administered and central vascular catheters were removed within 2 days of the first positive blood culture, outcomes such as end-organ dissemination and mortality were not increased.²¹³ With improved blood culture methods, the majority of blood cultures that are a positive for a *Candida* species will be positive within 2 days of collection.

Diagnosis

Cultures of blood, urine, CSF, and peritoneal fluid or other sterile body fluids remain the best method for diagnosing IC (see Fig. 200.4). Focus on obtaining sufficient blood culture volumes (≥ 1 mL) and performance of urine and CSF cultures at the time of evaluation for sepsis remain critical to making a prompt diagnosis. In the setting of candidemia, dissemination can occur, and screening for end-organ dissemination is warranted. Most commonly, with BSI, an initial screen including a lumbar puncture, echocardiogram, abdominal ultrasound scan, cranial ultrasound scan, and ophthalmologic examination is needed.

Treatment and Prevention

Amphotericin B Preparations

AmB-d should be started at 1 mg/kg, and LFAMB should be started at 5 mg/kg.^{19,47,227} Linder and colleagues¹⁸⁵ demonstrated that dosing of

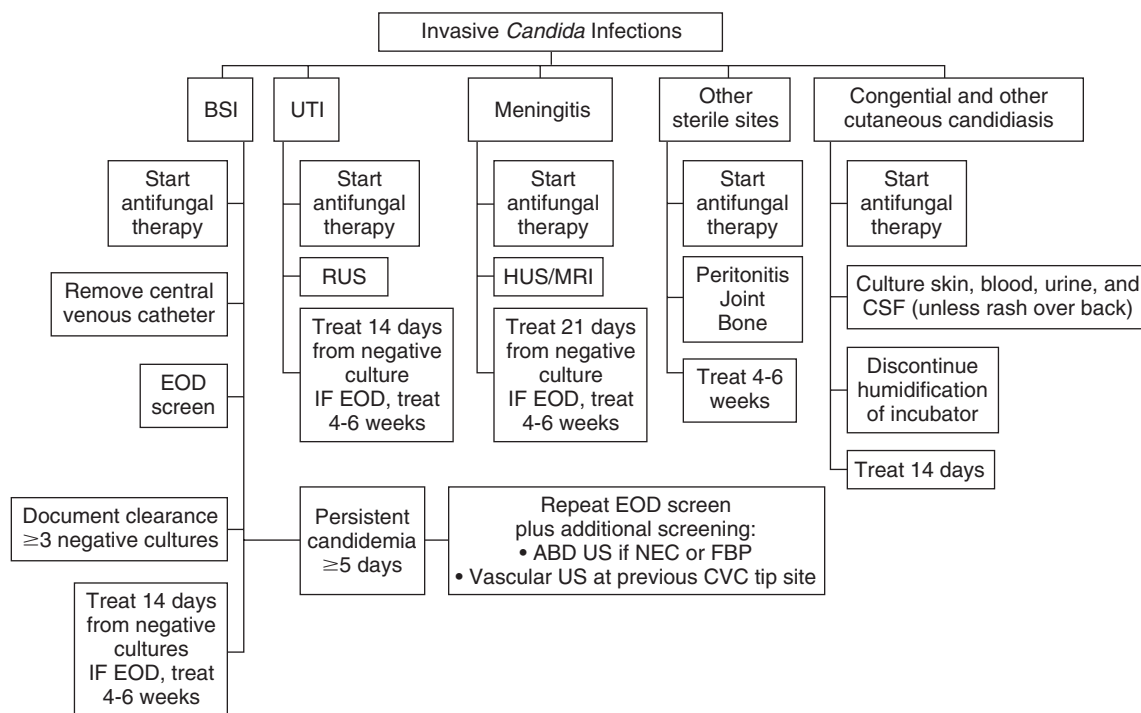

FIG. 200.4 Algorithm for evaluation and treatment of invasive candidiasis in neonates. Initial therapy pending susceptibilities: amphotericin B deoxycholate (ABD; 1 mg/kg/day). Alternatives: amphotericin B lipid preparations (5 mg/kg/day) or fluconazole (12 g/kg/dose). With meningitis or persistent candidemia lasting >7 days, combination therapy with a second antifungal (fluconazole) can be considered. With bowel disease such as necrotizing enterocolitis (NEC) or focal bowel perforation (FBP): complete abdominal ultrasound (US) for abscess should be performed. BSI, Bloodstream infection; CCC, congenital cutaneous candidiasis; CSF, cerebrospinal fluid; CVC, central venous catheter; EOD, end-organ dissemination; HUS, head ultrasound; MRI, magnetic resonance imaging; RUS, renal ultrasound; UTI, urinary tract infection.

1 mg/kg of AmB-d ($n = 34$) did not affect renal function. Creatinine levels (mg/dL) remained unchanged from the start of treatment (0.8 ± 0.4), at 24 hours after beginning treatment (0.8 ± 0.4), and again at the end of therapy (0.6 ± 0.2). This is an important difference compared with older children and adults, in whom infusion-related reactions and nephrotoxicity are frequent concerns with AmB-d. Lower “test” dosages of AmB-d are not needed in infants. Moreover, lower dosages in neonates only delay the time to achieve optimal therapy and may contribute to morbidity and mortality by delaying clearance of *Candida* species. LFAMB has less reliable penetration into the kidney,³³⁴ and this property has led most experts to recommend these formulations only in the setting of negative urine culture results and without evidence of renal parenchymal involvement.

Azoles

Fluconazole is commonly used to treat candidiasis in infants.³²⁹ The two most common species of *Candida* found in infants, *C. albicans* and *C. parapsilosis*, are almost always sensitive to fluconazole. However, 50% of *C. glabrata* and 100% of *C. krusei* isolates are resistant to fluconazole.²⁵⁸ Infants require 12 mg/kg per day to achieve exposures similar to older children and adults,³²⁰ and a loading dose of 25 mg/kg has been shown to achieve steady-state concentrations sooner than the traditional dosing scheme.^{237,321} Voriconazole has a wider spectrum of activity against *Candida* than fluconazole and is active in vitro against some isolates of *C. glabrata* and *C. krusei* that are resistant to fluconazole. However, the pharmacokinetics of voriconazole has not been described in infants.^{29,83,150}

Echinocandins

The echinocandins have efficacy against all *Candida* species, although the potential exists for resistance of *C. parapsilosis* isolates with acquired gene mutations. Of the echinocandins, the pharmacokinetics of micafungin is the most extensively described in infants.¹³⁴ In a rabbit model

of *Candida* meningoencephalitis, adequate systemic exposure of micafungin (area under the curve during 24 hours [AUC_{0-24}]: >170 $\mu\text{g}/\text{mL}$ per hour) was associated with 90% decreased fungal burden in brain tissue.¹³⁴ In a pharmacokinetic study, up to 15 mg/kg of micafungin was well tolerated in premature infants.²⁸¹ The recommended dose of micafungin in infants is 10 mg/kg per day to achieve adequate systemic exposure for the CNS.^{134,32} In a study of infants less than 3 month of age who were administered caspofungin at 25 mg/m² per day, caspofungin peak concentrations were lower and trough concentrations were higher compared with older children receiving 50 mg/m² per day.²⁵⁹ Anidulafungin has been studied in eight infants, but additional study is needed to determine appropriate dosing in infants.⁶⁸ Guidelines do not recommend echinocandins as initial therapy for neonatal candidiasis²²⁶ because of concerns about penetration in the CSF, although multiple animal models have demonstrated brain parenchyma penetration.

Central Venous Catheter Removal With Bloodstream Infections

Several studies have demonstrated that prompt removal of a central venous catheter is associated with lower mortality rates, a shorter duration of infection, and reduced end-organ dissemination.^{30,55,149,213} National Institute of Child Health and Human Development Neonatal Research Network data showed that the mortality rate was reduced from 37% to 21% ($P < .024$) when catheters were removed promptly (<24 hours) compared with delayed removal.³⁰ The combined outcome of neurodevelopmental impairment and death was associated with delayed removal or replacement of catheters.

Empiric Antifungal Therapy

The value of empiric therapy and its ability to improve outcomes in neonatal candidiasis continue to be investigated. Some studies have suggested that empiric antifungal therapy may lower mortality rates and improve outcomes in VLBW infants ultimately confirmed to have *Candida* sepsis, but these issues have not been investigated in controlled

trials.^{27,120,190} Clinicians have proven inaccurate in administering empiric therapy to infants who subsequently diagnosed with candidiasis. In a cohort of more than 1500 ELBW infants, only 29% of infants with candidiasis received empiric antifungal therapy.³¹

Prevention

As with other infectious diseases, prevention is key to achieving the best clinical outcomes. Morbidity and mortality rates are high, and for ELBW infants, 73% do not survive or survive with neurodevelopmental impairment.³¹ To date, antifungal prophylaxis is the only intervention that has been subjected to evidence-based randomized controlled trials for the prevention of IC. Prophylactic antifungal therapy has been shown to reduce both colonization and IC in the high-risk preterm infants. At birth, most infants are not colonized or have low colony counts of yeast, thus making them ideal candidates for antifungal prophylaxis. In the absence of antifungal prophylaxis, up to 60% of ELBW infants become colonized in the first 2 to 3 weeks after birth.¹⁵⁷ Prophylaxis prevents IC by decreasing *Candida* colonization of the skin, gastrointestinal tract, and respiratory tract, and central venous catheter, as well as colonization at multiple (two or more) sites.^{193,14,157,192,193}

Fluconazole prophylaxis. Currently there are more than 20 studies examining fluconazole prophylaxis for the prevention of IC in more than 5000 neonates consistently demonstrating efficacy with an overall reduction in IC of 70% to 80%.^{*} The overall incidence of IC in the placebo or control (untreated) groups was 9.1% compared with 1.3% in the fluconazole prophylaxis groups ($P < .0001$).¹⁵⁶ Efficacy is highest in the smallest infants (<1000 g) and youngest infants (≤ 27 weeks) when prophylaxis is started shortly after birth and given to all high-risk patients. All these studies have demonstrated the safety of fluconazole prophylaxis and lack of emergence of resistance.^{154,157,158,160,194}

The first study of fluconazole prophylaxis against fungal colonization and infection in premature infants was a prospective, randomized, double-blind clinical trial involving 100 ELBW infants requiring central venous access or endotracheal intubation.¹⁵⁷ Infants were randomly assigned during the first 5 days of life to receive either 3 mg/kg fluconazole IV or placebo for up to 6 weeks. Results demonstrated that fluconazole prophylaxis significantly decreased invasive fungal infection. None of the infants in the treatment group developed infection compared with 20% of infants in the placebo group ($P = .008$). The efficacy of a twice-weekly dosing regimen was studied as a simplified schedule in a randomized controlled trial compared with the more frequent dosing schedule. The randomized controlled trial demonstrated that 3 mg/kg administered twice weekly was as effective in preventing ICs as the more frequent dosing schedule used in the previous study.¹⁵⁸ Manzoni and colleagues¹⁹³ in Italy performed a multicenter, randomized, placebo-controlled trial investigating two different fluconazole doses (3 and 6 mg/kg) compared with a placebo group. In 322 VLBW infants, fungal colonization was significantly decreased from 29.2% in the placebo-treated patients to 7.7% and 9.8% in the 3 and 6 mg/kg groups, respectively. IC was decreased from 13.2% in the placebo-treated patients to 7.7% and 9.8% in the 3 and 6 mg/kg groups, respectively ($P = .005$ for the 6-mg group and $P = .02$ for the 3-mg group vs. the placebo group). Fluconazole prophylaxis had similar efficacy for both the 3 and 6 mg/kg groups. In a trial of 6 mg/kg twice weekly in infants weighing less than 750 g at birth, the incidence of IC was significantly decreased in the treatment arm, but when considering the combined outcome of death or IC, no significant difference was noted in the study arms. Additionally, rates of long-term neurologic impairment did not differ between the treatment and placebo groups.³³

Safety of fluconazole prophylaxis. No significant adverse effects have been reported in randomized trials in infants treated with fluconazole prophylaxis compared with control patients. Preventing IC has not led to an increased incidence in other infections. The incidence of bacterial infections and NEC are similar in all studies between treatment and control groups. Fluconazole-related cholestasis has been examined closely in several studies. No cholestasis was seen between groups in the randomized controlled trials, and retrospective studies

have shown by multivariate analysis that cholestasis is related to other factors such as NEC and bacterial infections and not fluconazole prophylaxis.^{132,157,193,197}

Neurodevelopmental status and quality of life of survivors from the first randomized controlled trial were evaluated at 8 to 10 years of life.¹⁶¹ No differences were found in the Vineland Adaptive Behavior Scales-II scores for the fluconazole-treated group compared with the placebo group. No differences were noted between groups regarding emotional difficulties or behavior problems. In a second trial of 361 infants weighing less than 750 g at birth, there was no significant difference in the incidence of neurodevelopmental impairment between patients in the fluconazole and placebo study arms (31% vs. 27%; $P = .60$). This finding remained in models that controlled for antenatal steroids, cesarean section, and level of maternal education ($P = .87$). The proportion of infants in each cohort who developed cerebral palsy, blindness, or deafness in each group was also not statistically different.

Nystatin prophylaxis. Nystatin, an enteral or orally administered nonabsorbable antifungal agent, was the first antifungal studied for prophylaxis in premature infants and has been the subject of several randomized or quasirandomized clinical trials and observational studies. These studies have added to our understanding of antifungal prophylaxis by demonstrating the benefits of prophylaxis even in NICUs with low rates of infection, thus confirming the greater effectiveness of prophylaxis when it is started early (by 72 hours after birth) versus later, after colonization is detected.

Two large retrospective studies of nystatin prophylaxis demonstrate the use of antifungal prophylaxis even in NICUs with low *Candida* bloodstream rates. In the largest multicenter observational study to date ($n = 14,778$) that compared preterm infants who received nystatin prophylaxis with those who did not receive any antifungal prophylaxis (1993–2006; Australia and New Zealand), oral nystatin prophylaxis was associated with a decrease in BSI or meningitis in infants weighing less than 1500 g (1.23%–0.54%; $P < .0001$) and in infants weighing less than 1000 g (2.7%–1.2%; $P < .0001$).¹⁴⁰ In a second study performed in a UK cohort of premature infants born at less than 33 weeks, nystatin prophylaxis was proven effective at reducing IC, and notably the all-cause mortality rate was significantly lower in the nystatin prophylaxis group (11.8%) compared with patients not receiving prophylaxis (17.8%) ($P < .0001$).¹¹²

Many questions regarding fluconazole and nystatin prophylaxis remain unanswered, but two studies have compared the two strategies. One randomized controlled trial of infants weighing less than 1500 g at birth compared oral fluconazole with oral nystatin prophylaxis started in the first 7 days and continued until full enteral feedings were achieved.³¹⁸ IC occurred in 2 of 38 (5.3%) fluconazole-treated infants compared with 6 of 42 (14.3%) nystatin-treated infants. No deaths occurred in the fluconazole-treated group compared with an all-cause mortality rate of 7.5% in the nystatin-treated group ($P = .03$). Of the six deaths, three were caused by NEC, one was caused by focal bowel perforation, and two were sepsis related. Only one of the six deaths was attributed to IC. One-third of the eligible patients for this study ($n = 44$) were excluded for hemodynamic instability or gastrointestinal concerns. The oral suspension of nystatin has a very high osmolarity of 3002 mOsm/L, and concern exists about the use of hyperosmolar medications and NEC.

Aydemir and associates,¹⁴ conducted a three-arm randomized controlled trial of antifungal prophylaxis in infants weighing less than 1500 g. Patients were randomized to fluconazole ($n = 93$), nystatin ($n = 94$), or placebo ($n = 91$). This study demonstrated that fungal colonization was less common in the fluconazole (10.8%) and nystatin (11.7%) prophylaxis groups compared with the placebo arm (42.9%). The rate of IC was significantly lower in both the fluconazole (3.2%) and nystatin (4.3%) groups compared with the placebo-treated (16.5%) patients. Although a previous study had raised concerns regarding nystatin use and NEC and all-cause mortality,³¹⁸ this study demonstrated no differences among groups in the incidence of NEC (fluconazole, 8.6%; nystatin, 9.6%; placebo, 9.9%) or mortality rates (fluconazole, 8.6%; nystatin, 8.5%; placebo, 12.1%).

Although oral fluconazole for prophylaxis was used in one of the foregoing studies, almost all other fluconazole prophylaxis studies have

*References 3, 14, 15, 25, 36, 38, 131, 132, 157, 163, 191, 193, 197, 252, 307, 318, 328.

used intravenous administration in the first weeks. Even though enteral fluconazole is 90% absorbed, absorption characteristics in preterm infants are variable and not well studied. Additionally, as discussed earlier, enteral administration of fluconazole prophylaxis may not be an option if patients have an ileus, NEC, intestinal perforation, or hemodynamic instability. It is during these clinical situations that fungal colonization, proliferation, and dissemination are most likely to occur. For these reasons and to prevent colonization of central venous catheters, the intravenous route is recommended for fluconazole prophylaxis in preterm infants when peripheral or central intravenous catheters are present. In some studies, fluconazole was changed to enteral administration once patients achieved full enteral feedings and intravenous access was discontinued.

Assessing the evidence collectively, fluconazole is recommended as the preferred prophylaxis agent over nystatin, given the greater effectiveness of fluconazole in preventing IC (80–90% compared with 50–60%), safety in infants weighing less than 1000 g, twice-weekly administration, and ability to administer to all high-risk infants weighing less than 1000 g, even in the presence of gastrointestinal disease or hemodynamic instability.

Infection control measures to prevent neonatal invasive candidiasis

Prenatal detection and eradication of maternal vaginal candidiasis. In pregnancies complicated by preterm labor or prolonged rupture of membranes, screening and treatment of vaginal candidiasis may be beneficial in preventing candidal colonization and subsequent infection in the newborn (Box 200.2).^{41,105,322}

Medication and feeding stewardship. Practices reducing medications that increase the risk for IC should be avoided if possible and instituted with stewardship, guidelines, tracking or auditing, and accountability.¹⁵⁶ Medications that increase risk for IC, as discussed previously, include: broad-spectrum antibiotics (third- or fourth-generation cephalosporins or carbapenems), gastric acid inhibitors (H_2 blockers and proton pump inhibitors), and postnatal dexamethasone.¹⁵⁶ Data from a multicenter

randomized trial of postnatal hydrocortisone in infants weighing less than 1000 g did not associate hydrocortisone exposure with an increased rate of candidemia; both the hydrocortisone-treated group and the placebo group had an incidence of *Candida* BSIs of 10%.³²⁶ Implementation of early feeding protocols (starting early and trophic and slow feed advances) and promoting breast milk feedings may aid in decreasing the risk for IC as well.

Central line–associated bloodstream infection bundles. Standardized protocols for insertion and management of central venous catheters, attention to sterile practices, hub and dressing care, and closed medication delivery systems may reduce central line–associated BSIs, including *Candida*-related BSIs.^{6,62} Aly and colleagues⁶ reported a significant reduction in all central line–associated BSIs and elimination of *Candida* infection by using a “bundled approach” that included antifungal prophylaxis in addition to line placement and maintenance interventions.

Lactoferrin. In a randomized controlled trial of bovine lactoferrin (bLF) in infants weighing less than 1500 g, the incidence of late-onset sepsis was significantly lower in the bLF and bLF plus probiotics groups than in the placebo-treated patients.¹⁹⁵ Subanalysis found that invasive fungal infections were also significantly less common with bLF alone compared with placebo. One limitation of the study was that it contained only between 9 and 18 infants weighing up to 750 g in each group. Confirmation of the findings in extremely preterm infants is needed.

Outcomes

Neurodevelopmental Impairment

IC may lead to significant neurodevelopmental impairment even in absence of documented fungal meningitis. Neurodevelopmental impairment in most studies is the presence of one or more of the following: low mental and motor development using Bayley Scales of Infant Development II, cerebral palsy, deafness, and blindness. Using these criteria, the incidence of neurodevelopmental impairment is 57% in patients with IC versus 29% in noninfected ELBW infants^{292,30} (Fig. 200.5). The incidence of neurodevelopmental impairment was similar for the subset of patients with *Candida* meningitis (53%). These data are similar to those from a study from an earlier time period.¹⁰⁸ Neurodevelopment was intact in 41% of *Candida*-infected patients and in 65% of controls ($P = .02$). The frequency of periventricular leukomalacia was increased in the patients with IC, but this difference did not reach statistical significance (26% vs. 12%; $P = .06$). In this study neurodevelopmental outcome was related to timing of initiation of antifungal therapy. Commencement of antifungal therapy was 5.1 ± 3.0 days after blood culture was drawn in those infants who had severe disabilities or who died compared with 2.1 ± 1.3 days in those infants who were normal or mildly impaired ($P < .0001$).

FIG. 200.5 Neurodevelopmental impairment and candidemia in infants weighing <1000 g. Neurodevelopmental impairment: one or more of the following: Bayley Scales of Infant Development II physical or mental developmental index <70, cerebral palsy, or visual or hearing impairment. Clinical infection: late-onset infection with negative culture results with antibiotic treatment for ≥ 5 days. CoNS, Coagulase-negative staphylococci; * $P \leq .001$ compared with the no-infection group.

BOX 200.2 Strategies to Reduce Neonatal Invasive Candidiasis Morbidity and Mortality

1. Use antifungal prophylaxis (IV fluconazole) while IV access is in use (central or peripheral) for infants with birth weight <1000 g and/or ≤ 27 weeks' gestational age
 - a. There is A-I evidence for antifungal prophylaxis with nystatin but limited data in infants <750 g and <26 weeks' gestation. Because fluconazole prophylaxis has greater efficacy compared with nystatin, efficacy in the most immature patients, and can be given to infants not feeding, current evidence currently favors fluconazole prophylaxis in preterm infants weighing <1000 g.
2. Start treatment of documented infections with appropriate antifungal dosing and prompt catheter removal for candidal BSI.
 - a. Consider starting empiric antifungal therapy if invasive candidiasis is suspected.
 - b. Promptly treat congenital cutaneous candidiasis.
3. Decrease broad-spectrum antibiotic use. Restrict third- and fourth-generation cephalosporins and carbapenems to treatment of proven gram-negative infections.
4. Decrease H_2 blocker and proton pump inhibitor use. Use only for proven gastritis, and restrict use to 3 days or until symptoms resolved.
5. Decrease postnatal dexamethasone use. Use only for severe lung disease.
6. Institute central line associated bloodstream infection reduction bundles
7. Monitor rates of invasive candidiasis including candidemia, UTI, meningitis and peritonitis infections and feedback to staff.

Level of evidence. US Public Health Service Grading System for ranking recommendations in clinical guidelines: Strength of recommendation and levels of evidence. A: good evidence; B: moderate evidence; C: poor evidence. I: at least one randomized clinical trial; II: at least one well-designed but nonrandomized trial; III: expert opinions on the basis of experience or limited clinical reports.

BSI, Bloodstream infection; IV, intravenous; UTI, urinary tract infection.

Survival

Mortality rates are high among ELBW infants with IC. A multicenter study of patients weighing less than 1000 g found that the overall mortality rate was 34% for infants with IC compared with 14% without IC.³¹ All-cause mortality rates were 28% for infants with candidemia, 26% for those with *Candida* UTI, and 50% for those with other sterile site infections (meningitis and peritonitis). If two or more culture sites tested positive (blood plus urine or urine plus CSF), the mortality rate rose to 57%.

There is a marked difference in overall and attributable mortality for IC between infants weighing less than 1000 g and those infants who are larger and more mature. In infants weighing less than 1000 g with IC, one analysis reported an all-cause mortality rate of 26% compared with 13% in infants without candidiasis. For infants weighing more than 1000 g with IC versus those without, the mortality rate was 2% compared with 0.4%.³³⁸

Candida-Related Mortality

Assessing attribution of death to *Candida* is difficult and varies by publication. Some researchers have linked attribution to death within a specified number of days from the onset of infection (3, 7, 14, or 30 days) or review each death and assign attribution by using predetermined definitions. Furthermore, published attributable mortality rates of IC vary depending on the study type. In observational cohorts of infants weighing less than 1000 g mortality rates have been documented to be between 13% and 15%,^{31,338} whereas in the placebo or control arms of randomized trials of prophylaxis agents, the mortality rates range from 23% to 66%.¹⁵⁴

Coccidioidomycosis is an infection caused by a dimorphic fungus of the genus *Coccidioides*. The primary pulmonary infection produced by this organism usually is self-limited, but disseminated and fatal disease can occur. In the United States, coccidioidomycosis is an endemic disease of the southwestern states and results in 150,000 infections per year.⁷² In other parts of the United States, it is seen in individuals who have traveled to or lived in the endemic areas of the Southwest or Mexico.^{28,35,54} The disease is endemic in other areas of the Western Hemisphere, most notably in northern Mexico and in certain countries in South and Central America.¹³³

Pulmonary disease is underrecognized even in areas of high endemicity.^{107,171} With population growth in the endemic areas of the Southwest and increased population mobility, clinicians in nonendemic areas are likely to encounter this disease, particularly in its more severe or disseminated forms. Reactivation, especially in the immunocompromised host, can result in disease long after primary infection, emphasizing the need for a thorough travel history.

Coccidioidal granuloma, a form of disseminated coccidioidomycosis, was described first by Posadas in 1892 in Argentina.⁸⁸ The disease initially was thought to be a form of skin tumor. Rixford and Gilchrist associated it with what they thought was a protozoon resembling coccidia and named it *Coccidioides*. In 1900, Ophüls and Moffitt were the first to attribute coccidioidal granuloma to the fungus *Coccidioides immitis*. Although earlier investigators had observed fungal growth on cultures from pathologic specimens, they were dismissed as contaminants. Between 1900 and 1936, numerous reports of coccidioidal granuloma appeared in the medical literature, but the association between coccidioidal granuloma and acute pulmonary infection remained unrecognized. In 1936, Gifford⁷⁹ and Dickson were the first to designate *C. immitis* as the causative agent of what had previously been known in California as San Joaquin fever or valley fever.^{74,88}

In the period that followed, the epidemiology of the disease^{153,156} and ecology of the organism^{61,117} were studied carefully by many investigators, led by the efforts of Charles Smith.⁸⁸ Many different therapies were attempted for disseminated disease during this era, but none proved satisfactory.⁶¹ In 1957, with the use of amphotericin B, effective antifungal therapy became available, and the prognosis associated with disseminated disease improved.

As with many pathogenic fungi, the life cycle of *C. immitis* demonstrates two distinct phases: saprophytic, or vegetative, and parasitic. In nature and on most laboratory media, the organism grows as mycelia with branching, septate hyphae. After 5 to 7 days, the aerial mycelia show development of rectangular spores (i.e., arthrospores or arthroconidia) separated by empty, nonviable cells (Fig. 201.1). At this stage, the hyphae become fragile, and the arthroconidia easily become airborne. Their size (2–8 µm in diameter) allows them to reach the alveolar spaces of the lung when they are inhaled.

On gaining access to mammalian host tissues, the arthroconidia begin the parasitic phase of their life cycle. They enlarge and develop into spherules during the course of approximately 48 hours while undergoing internal segmentation to form endospores that are 2 to 5 µm in diameter. The spherules (Fig. 201.2) are round, double-walled structures measuring 20 to 100 µm in diameter. Endospores are released into the surrounding tissues by rupture of the spherule wall, where they mature into more spherules, repeating the tissue phase of the life cycle.¹⁴⁷

Coccidioides spp. grow on laboratory media relatively easily, producing nonpigmented colonies that become visible in 3 to 4 days. They represent the mycelial phase of the fungus and appear as flat, smooth, and gray colonies from which spicules may project in some, whereas others have a velvety, membranous appearance. Colonies appear as tufts in the

second week and then develop cobweb-like aerial hyphae. Pigmentation can be seen after 2 weeks and is observed best as a brownish undersurface. Variability in colony morphology can be significant.

Of the two species of *Coccidioides*, *C. immitis* is prevalent in California, and *C. posadasii* accounts for isolates from Arizona, Texas, Mexico, and parts of Central and South America.⁶⁷ No clinical differences have been recognized between the two species. Identification is accomplished using reliable techniques showing in vitro conversion to the spherule stage, demonstration of specific exoantigens, or identification of the organism by genetic probes, any of which obviate the need for animal inoculation.¹⁴⁷

EPIDEMIOLOGY

Coccidioidomycosis is endemic in the Western Hemisphere between 40 degrees of latitude north and south. In the United States, these areas lie in the southwestern states, especially in Arizona, California, western Texas, and southern New Mexico. The organism also has been found in soil in areas not classically thought of as endemic, such as south central Washington state,¹²⁰ where a cluster of cases has been identified.¹²¹ Other cases have occurred in nonendemic areas, such as Missouri.¹⁷⁰

The areas in which coccidioidomycosis is prevalent generally correspond to the lower Sonoran life zone.¹³³ This life zone is characterized by an arid to semiarid climate, with hot summers and relatively short winters with limited rainfall and few freezes. Most fungal growth occurs during the rainy season in alkaline soil and at low altitude. The fungus is found in the soil to a depth of 20 cm, especially in the walls of rodent burrows. Environmental conditions in endemic regions apparently inhibit the growth of competitive organisms.^{61,67} A variety of animals, including rodents, cattle, sheep, and dogs, are susceptible to naturally acquired infections.

Arthroconidia become airborne during wind storms or during disruption of soil by construction work, farming, and earthquakes.^{34,68} Prolonged droughts followed by heavy rains also have resulted in an increased number of cases, as occurred in California in 1992 and 1993.³³ Archeologic excavations and digging by children in soil containing the organism have resulted in local outbreaks.^{36,187} Transmission also has occurred by contaminated fomites, such as dusty clothing and farm products.^{1,144}

The ease with which arthroconidia become airborne makes the organism dangerous to laboratory personnel. Epidemics have resulted from inadvertent opening of a single culture plate.¹⁰¹ Guidelines for management of accidental laboratory exposures have been published.¹⁶²

Primary coccidioidal infection occurs most frequently in summer and fall, after the rainy seasons. Arthroconidia are more likely to become dispersed during dry weather after promotion of greater hyphal growth by a wet environment.^{61,153,154} Variations in seasonal incidence are partially explained by the occurrence of dust storms^{133,135,154} and earthquake activity.³⁴

Susceptibility to primary coccidioidal infection is unaffected by age, sex, or racial background.⁶⁶ Estimates of infection rates in endemic areas, which are based on the risk of infection in children, had declined as urbanization developed with dust abatement and paved roads. For example, infection rates measured by coccidioidin skin test reactivity declined from approximately 10% in 1937 through 1939 to 2% in 1959 and to less than 1% thereafter among kindergarten and first-grade students who had lived all of their 5 to 7 years in Kern County, California.¹¹² Similarly, the annual risk has been estimated to be between 2% and 4% among college students in Tucson, Arizona.¹⁰⁶ Incidence rates are higher for older male children, in rural areas, during wind

FIG. 201.1 In the mycelial form of *Coccidioides immitis*, arthroconidia are separated by vacuolated cells. (From Davis BD, Delbecco R, Eisen HW, et al., eds. *Microbiology, Including Immunology and Molecular Genetics*. 3rd ed. Hagerstown, MD: Harper & Row; 1980.)

FIG. 201.2 Coccidioidal granuloma shows a multinucleated giant cell containing a spherule filled with endospores. The adjacent field consists of granulomatous inflammation.

storms, and for those with occupational exposure.^{121,142,153} Significant increases in the number of reported cases have been observed in Arizona and California, from 5.3 per 100,000 in 1998 to 42.6 per 100,000 in 2011.^{69,87}

In contrast to susceptibility to primary infection, the frequency of dissemination and severe disease varies considerably and is higher among infants,^{42,43,97,153} Filipinos, Hispanics, and blacks. Immunosuppressed hosts also are at increased risk for disseminated infection. Persons receiving anti-tumor necrosis factor- α (TNF- α) therapy are at increased risk for severe pulmonary coccidioidomycosis.^{13,127} In the era of potent antiretroviral therapy, the severity of the disease has decreased among human immunodeficiency virus (HIV)-infected individuals and is inversely associated with control of the infection.¹²³

The tissue phase of the organism is the spherule, which is not infectious. Although mycelial growth can be found in cavities when they are carefully searched, no evidence exists of person-to-person spread of *C. immitis*,^{84,186} except in special situations in which the fungus is

allowed to revert to its airborne form, such as growth from wound drainage on a plaster cast.⁶⁰ Patients with coccidioidomycosis do not require isolation, even when draining wounds exist. In these circumstances, dressings should be changed frequently to prevent growth of the fungus and the formation of arthroconidia.

Once limited to the lower Sonoran life zone, the disease is seen throughout the country because of the ease and frequency of travel, increased populations in endemic areas, and reactivation of infection in immunocompromised hosts, including transplant recipients, patients with acquired immunodeficiency syndrome (AIDS), and recipients of TNF- α inhibitors. For these patients, delays in establishing the diagnosis can be fatal, and rapid recognition of the diagnosis and prompt institution of appropriate therapy mandate a timely and accurate diagnosis.

PATHOGENESIS AND PATHOLOGY

Acquisition of *Coccidioides* spp. infection usually occurs through the respiratory tract. It is surmised that most human infections result from exposure to only a single spore.⁷² Growth of the organism stimulates an intense inflammatory response, and in most patients, the infection remains localized to the lung and hilar nodes. This bronchopneumonic process can occur in any lobe of the lung. In a few patients, clinically significant extrapulmonary dissemination occurs by way of lymphatics or the bloodstream. Rarely, direct cutaneous inoculation may occur by puncture of the skin with a contaminated object, which results in localized disease with occasional sporotrichoid spread.^{39,130}

The initial inflammatory response of acute pulmonary coccidioidomycosis consists primarily of a neutrophilic reaction, possibly related to a chemotactic effect of endospores or complement activation from other *Coccidioides* antigens. Tissue necrosis, spherules, and a few mononuclear cells are present at this stage of the disease, but epithelial giant cells are infrequently seen. Although this response may slow the progress of the infection temporarily, it ultimately cannot arrest the disease process⁷² because neutrophils do not kill coccidioidal forms.

Killing has been demonstrated with natural killer cells and mononuclear leukocytes. Numerous studies have demonstrated the importance of T-cell-mediated responses, particularly the Th1 response, in controlling the infection, as evidenced by delayed cutaneous hypersensitivity, peripheral lymphocyte transformation, and production of interleukin-12, interferon- γ , and TNF- α .⁷² Dermal hypersensitivity correlates well with other measures of peripheral blood lymphocyte responsiveness, such as lymphocyte transformation and cytokine production.³ In patients with progressive disease, cell-mediated immune defenses become defective, possibly because of defective antigen presentation, antigen overload, suppressor cells, immune complexes, or fungal immunomodulatory substances, resulting in an undesirable and ineffective Th2 response.⁴⁸ Cytokines, including interferon- γ and tumor necrosis factor- α , are important in protection and control of infection by enhancing Th1 and Th17 immune responses.¹⁷⁶ The role of the Th17 response in acute infection remains controversial, but it may have a beneficial effect in preventing primary infection in murine models.^{92,180}

Disseminated coccidioidomycosis resembles progressive tuberculosis of childhood, which usually occurs within weeks or months after the initial infection develops. However, endogenous reactivation also can occur, particularly among individuals with immunosuppressive conditions.^{3,21,73} Extrapulmonary spread can occur anywhere in the body, but lesions are found most frequently in bone, soft tissue, lymph nodes, liver, spleen, and meninges. Bone lesions resemble chronic osteomyelitis (Fig. 201.3). Infection of the brain parenchyma is a rare event, but meningitis occurs commonly and frequently localizes to the basilar area.^{23,93}

The pathologic findings of fatal coccidioidomycosis have been reviewed extensively.⁹⁴ The tissue reaction in disseminated disease predominantly is granulomatous but can be accompanied by elements of acute inflammation. Typically, the granulomatous lesions contain abundant giant cells and histiocytes. Caseous necrosis is a common occurrence, and spherules usually can be identified lying freely and within macrophages or multinucleate giant cells (see Fig. 201.2). Fibrous tissue can surround areas of inflammation, but calcification is an infrequent occurrence.

FIG. 201.3 An osteolytic lesion involving the distal radius in a 14-year-old boy with osteomyelitis and disseminated coccidioidomycosis.

Most cases of disseminated coccidioidal infection in the first months of life have been associated with heavy exposure to dust; these infants apparently acquire their infection by the respiratory route.^{44,97} Most infants described have had severe disease,^{42,43,97,167} but primary infection sometimes is unrecognized.⁴³ Although women who develop coccidioidomycosis late in pregnancy may be at increased risk for development of disseminated disease,¹⁷⁸ with a few exceptions,^{40,115} their infants are born free of infection.^{44,45,152,172} In several patients with apparent perinatal transmission, the mothers had coccidioidal endometritis, and infected amniotic fluid was the most likely source of their infants' infections.^{14,115,149,160}

Dissemination of coccidioidomycosis occurs more frequently in immunosuppressed patients who have resided in an endemic area.^{73,119} No specific immunologic abnormalities have been detected in other groups, such as Filipinos, who also are at high risk for disseminated disease. Gain-of-function mutations in the *STAT1* gene, resulting in aberrant regulation of the interferon- γ and interleukin-12 axis, have been identified in patients with disseminated disease.¹⁴⁶ After dissemination occurs, the patient's cell-mediated immunity is frequently impaired,^{3,32,47,48,158} especially if infection is extensive.^{10,156}

Dissemination can occur in patients who have a selective lack of response to coccidioidal antigens, as evidenced by negative skin test results to coccidioidin or spherulin, without evidence of generalized anergy. In vitro measurements of lymphocyte transformation to phytohemagglutinin or to specific cell wall antigens of *C. immitis* are also depressed.^{10,47} In contrast, patients with disseminated disease with positive skin test results usually have normal in vitro lymphocyte responses that are similar to those found in healthy persons who have recovered from primary infection.^{48,131,190} Patients who have recovered from severe disseminated disease may show return of specific and nonspecific cell-mediated immunity.^{10,32,66,158} Infected children demonstrate immunologic findings similar to those described in adults, but they have not been studied as extensively.

CLINICAL MANIFESTATIONS

Primary Pulmonary Infection

The clinical features of acute coccidioidomycosis in children are thought to be similar to the manifestations observed in adults.¹⁵⁵ Studies of Air Force personnel indicate that infection is subclinical or indistinguishable from a mild upper respiratory tract infection in 60% of infected

persons.^{156,158} Twenty-five percent experience an influenza-like illness lasting 1 to 2 days, whereas the remainder have more severe lower respiratory illnesses, including lobar pneumonia, pleural effusions, and occasionally, pericarditis.^{66,72,156} With intensive exposure, such as occurs during military field exercises, the attack rate may be high, and a large proportion of infections may be symptomatic.⁵⁰

The disease may mimic bacterial pneumonia and sepsis.^{6,116} When serologic studies are used routinely in the evaluation of adults with community-acquired pneumonia in endemic areas, 17% to 28% of cases are the result of coccidioidal infection.^{107,171} However, only 2% to 13% of adults with community-acquired pneumonia are tested for coccidioidomycosis, even in highly endemic areas.³⁸ Although most symptomatic pulmonary infections are subacute and self-limited, some patients experience more complicated pulmonary infections or have extrapulmonary disease.⁶⁹ Outside of endemic areas, these patients are likely to undergo extensive workups, and delays in establishing the diagnosis can occur if coccidioidomycosis is not considered.^{27,28,54} Severe disease is more likely to develop in individuals with diabetes, a recent history of cigarette use, or immunocompromising conditions.¹⁴³

The usual incubation period is 10 to 16 days, but it may range from less than a week to almost a month.⁶⁶ In young adults, fatigue (77%), cough (64%), chest pain (53%), and dyspnea (17%) are the most common symptoms. Fever occurs in 46%, with arthralgias, myalgias, and headaches each reported for 22%.¹⁶⁶ Chest pain sometimes is severe and is usually pleuritic.¹⁶⁶ It may be followed by vague chest pain that persists for several months.⁷² Primary pulmonary coccidioidomycosis resembles other lower respiratory illnesses, including those caused by viruses, bacteria, mycoplasma, *Mycobacterium tuberculosis*, and other fungi (e.g., *Histoplasma*). In infants, stridor rarely may be the result of primary infection of subglottic tissue.^{78,85}

Transient rashes probably occur more frequently in children than in adults and are observed in slightly more than one half of symptomatic children.^{56,90,140} The rash can manifest as erythema nodosum, erythema multiforme, toxic erythema, Sweet syndrome, or reactive interstitial granulomatous dermatitis. Erythema nodosum is the most characteristic lesion. It usually appears 1 to 3 weeks after the onset of illness and is associated with a lower risk of disseminated disease.^{9,56,66,90,153} Erythema multiforme-like lesions are common in children, as is toxic erythema, a macular, papular, urticarial, or morbilliform rash that manifests within 48 hours of onset of symptoms. It may last for several weeks and is followed sometimes by palmar desquamation.⁵⁶

Acute arthritis or arthralgia can accompany primary coccidioidal infection. These findings usually are transient, do not signify dissemination, and are thought to represent a hypersensitivity reaction.⁵⁸

The radiographic appearance of primary coccidioidomycosis is nonspecific.^{11,41,83,140} Bronchopneumonic infiltrates are the most frequent finding and often are associated with hilar lymphadenopathy. Segmental or lobar consolidation and nodular or patchy pulmonary infiltrates also can occur. Small pleural effusions or pleuropericardial reactions occur in 15% of hospitalized patients (Fig. 201.4) and are usually sterile.¹²⁶ These radiographic findings resolve in 90% to 95% of symptomatic cases, albeit slowly in some, and usually do not necessitate specific therapy. Mediastinitis with necrotizing mediastinal adenitis was diagnosed in 21% of children admitted for coccidioidomycosis to a central California hospital, a rate much higher than is reported for adults.¹²⁵

In neonates, the constellation of radiographic findings of focal consolidation with diffuse nodular densities, nonspecific symptoms, and minimal clinical evidence of respiratory tract infection has been described but is not specific for coccidioidomycosis.^{14,41} Chorioretinitis as a manifestation of systemic disease has also been reported.⁸⁰

In some patients, cavitation, nodule formation, bronchiectasis, or calcification can develop at the site of the pulmonic infiltrate.¹⁶ The cavities usually are asymptomatic and rarely require surgical therapy. Nodules and thin-walled cavities develop in 5% of patients with coccidioidal pneumonia. The well-circumscribed lesions are typically single and less than 6 cm in diameter. Many resolve spontaneously, but patients nonetheless require prolonged care and convalescence. Rarely, the cavities lead to pneumothorax (Fig. 201.5), empyema, or bronchopleural fistulas, which are more likely to occur in immunosuppressed patients or in diabetics.⁹⁸ In adults, nodules may be confused with carcinoma of the

FIG. 201.4 Chest radiograph of a patient with acute pulmonary coccidioidomycosis showing pulmonary infiltrates, extensive pleural fluid, and enlargement of the left hilum. Drainage was not attempted, and the chest radiograph normalized after 3 months of treatment with fluconazole alone.

FIG. 201.5 A right lower lobe thin-walled cavity resulting in pneumothorax in an otherwise healthy 17-year-old boy.

lung, requiring excision or diagnostic fine-needle aspiration.⁵⁷ A miliary pattern, indicating hematogenous or lymphatic spread, sometimes can be appreciated in immunocompromised hosts and rarely in immunocompetent hosts.⁸ Occasionally, endotracheal or endobronchial lesions can be demonstrated by endoscopy.¹³⁷

The manifestations of primary coccidioidal disease vary. Because no constellation of symptoms and signs is specific enough to establish a diagnosis, specific laboratory tests are a requirement.

Primary Inoculation-Related Infection

Rarely, primary cutaneous coccidioidomycosis develops after direct inoculation of the skin (Fig. 201.6). Lesions develop 1 to 3 weeks after

FIG. 201.6 A chronic, right lower eyelid lesion resulting from traumatic inoculation at the site several weeks earlier. Tissue cultures grew *Coccidioides* spp.

FIG. 201.7 Verrucous cutaneous lesion at the nasolabial fold from coccidioidal hematogenous dissemination.

an injury and are often associated with localized lymphadenitis. Nodular lymphangitis mimicking sporotrichosis, cutaneous nocardiosis, and *Mycobacterium marinum* infection can occur.

In adults, constitutional symptoms usually are mild, and the process spontaneously resolves within 2 to 3 months. However, progressive and prolonged infection commonly occurs in children, and antifungal therapy may be necessary.^{130,185} Transmission by cat bite has been reported.⁷¹

Disseminated Coccidioidomycosis

Except in very young children, dissemination appears to occur less frequently in pediatric patients than in adults (0.5%), although this view has been questioned.^{102,151} Spread of infection usually becomes apparent within a few weeks to a few months after the initial infection occurs. It is heralded by persistent fever, toxicity, and insidious development of lesions outside the chest.

A few patients develop disseminated disease after having an asymptomatic primary infection.^{52,64,102} Disseminated disease rarely can manifest with peritonitis, pericarditis, empyema, laryngeal lesions, endocarditis, or soft tissue abscesses.^{25,51,91}

Skin Disease

The most common cutaneous manifestation of disseminated coccidioidomycosis is a verrucous granuloma that is characteristically located at the nasolabial fold (Fig. 201.7).^{66,90} These lesions may heal or may continue to progress. They can also take the form of papules, nodules, subcutaneous abscesses, pustules, or sinus tracts. They can be single or multiple and can ulcerate. Rarely, they appear similar to mycosis fungoides. Cutaneous lesions result from bloodborne dissemination and contain the organism. These lesions mimic those caused by other fungi, tuberculosis, actinomycetes, and syphilis.⁵⁶

FIG. 201.8 Swelling and chronic draining sinus is seen over the proximal phalanx of the index finger. The infant has disseminated coccidioidomycosis with involvement of the underlying bone.

Bone and Joint Disease

Involvement of bone results in chronic osteomyelitis,^{17,53,89,99} which can drain into soft tissue (Fig. 201.8) and fistulize to the overlying skin.⁵² The bones most frequently infected are the vertebrae, tibiae, metatarsals, skull, and metacarpals. The lesions are identified in a single bone in 60% of cases; two bones in 20%, three in another 10%, and four or more bones in the remainder. On radiographic examination, the lesions typically are lytic (see Fig. 201.3).

Involvement of the axial skeleton is common. Vertebral osteomyelitis is characterized by involvement of all parts of the vertebra with relative sparing of the disk, in contrast to tuberculosis. Spread of infection locally leading to meningitis is a serious concern with vertebral osteomyelitis. Skull involvement typically leads to erosion of the outer table. Arthritis has a waxing and waning course and usually involves the knee or ankle. It can result from direct inoculation of the joint, as in the case of a cactus spine. Periarticular disease, such as tenosynovitis, can also occur through inoculation or hematogenous dissemination.³⁰

Meningitis

Coccidioidal meningitis may be the sole site of extrapulmonary disease, particularly in whites, but it also occurs as part of widespread dissemination.^{23,100,150} It may manifest acutely with the primary infection or appear up to 6 months later.

The most common symptom is headache. Altered mental status, sluggishness, ataxia, and vomiting are other common symptoms. Children often lack signs of meningeal irritation and sometimes have focal neurologic deficits at presentation.

The pathologic process is that of granulomatous and suppurative basilar meningitis, with frequent parenchymal involvement with granulomas and abscesses of the spinal cord and brain.^{63,128} Vascular complications with infarction and stroke-like findings may be abrupt in onset.^{63,184} Hydrocephalus is common in children and is treated by placement of a ventriculoperitoneal shunt.¹⁵⁰

Before amphotericin B became available, coccidioidal meningitis was uniformly fatal, and the average length of survival in children was 5.5 months. Death with coccidioidal meningitis has become an uncommon event. However, adults with neuroimaging abnormalities, especially hydrocephalus with or without cerebral infarction, have a high mortality rate.⁷

Examination of the cerebrospinal fluid (CSF) usually reveals moderate pleocytosis, usually between 100 and 500 white blood cells/mm³ (with a range of a few to more than 10,000 white blood cells/mm³) with mononuclear cell predominance, hypoglycorrachia, and an elevated protein level.^{105,150} Polymorphonuclear cell predominance may occur early in the course of the illness. These findings are typical for CSF sampled from the lumbosacral space. However, considerable variation

occurs in the cell count, chemistry, and antibody content of fluid obtained from the ventricles, cisterna magna, or lumbosacral space.^{81,86,150} The lumbosacral space exhibits the most severe changes, including a lower glucose concentration, higher protein level, higher cell count, and higher CSF coccidioidal complement fixation titer.

Eosinophilic pleocytosis in the CSF suggests coccidioidal meningitis and should prompt an appropriate diagnostic workup; it is of no prognostic value.¹³⁹ The CSF culture often is negative for the fungus, whereas CSF antibody is detectable in up to 95% of patients.¹⁰⁵ The diagnosis is confirmed by a positive CSF culture or serology and is supported by a positive serum serologic result or culture of *Coccidioides* spp. from a pulmonary or nonpulmonary site.

Coccidioidomycosis in Pregnancy

Like tuberculosis, coccidioidomycosis can involve the pelvic organs. Early studies had indicated an alarming risk of dissemination in and death of women who acquired coccidioidomycosis, especially during the third trimester of pregnancy. In a population-based study, Wack and colleagues¹⁷⁸ showed that coccidioidomycosis occurs infrequently during pregnancy but remains associated with serious complications when the disease develops in the third trimester or soon after delivery. This is thought to be the result of immunosuppression and increased hormonal levels that favor the growth of spherules.¹⁶¹ Pregnant women with erythema nodosum are much less likely to experience disseminated disease than are those without.⁹

Wide variations are reported in the rates of dissemination and fatality for pregnant women, although all studies agree that the rate of dissemination for pregnant women is higher than that for the general population.^{29,49} Maternal infection is more severe when it is acquired late in pregnancy and most severe in the immediate postpartum period.¹²

Coccidioidomycosis in the Immunocompromised Host

Control of coccidioidal infection depends primarily on cell-mediated immunity. Conditions that result in immune suppression, particularly T-lymphocyte dysfunction, such as those in patients who have undergone hematopoietic stem cell transplantation (HSCT) or solid organ transplantation, predispose the individual to more fulminant forms of coccidioidomycosis.^{21,141} Infections may be primary or the result of reactivation. Solid organ transplant recipients are at the highest risk in the first year after undergoing transplantation, especially during primary infection. Dissemination also can occur late as a result of reactivation of a prior infection. The risk is increased by a prior history of coccidioidomycosis or a positive serologic reaction just before transplantation.²¹ By use of targeted prophylaxis with fluconazole, however, the overall rate of coccidioidomycosis after liver transplantation (2.4%), renal transplantation (3%), and HSCT (1.5%) can be significantly reduced.^{26,177}

An increased risk of acquiring severe symptomatic disease was described for patients receiving TNF- α antagonists.¹³ In HIV-infected patients, the severity of pulmonary disease is related inversely to virologic control, with greatly increased risk of severe pulmonary and extrapulmonary disease when the CD4 count is less than 250 cells/ μ L. The morbidity rate for HIV-1-infected patients receiving antiretroviral therapy and with CD4 counts of 250 cells/ μ L or higher is similar to that in non-HIV-infected persons.^{2,123}

In endemic areas, the risk of coccidioidomycosis among solid organ transplant recipients is 4% to 9%.^{21,173,177} Most cases occur in the first year after solid organ transplantation. One-third of the patients have disseminated disease, with a mortality rate of 13% among those with posttransplantation coccidioidomycosis.¹⁷⁷ Genetic factors, such as deficiencies in interferon- γ receptor 1 or in interleukin-12 receptor β_1 , have been recognized in some patients with refractory disseminated coccidioidomycosis.^{174,175}

DIAGNOSIS

In endemic areas where an awareness of the disease exists, the diagnosis of coccidioidomycosis usually is established readily by obtaining appropriate laboratory studies. However, even in these areas, coccidioidal pneumonia may be more prevalent than previously thought and can be underdiagnosed.^{107,171} Cases have occurred even after brief exposure

in an endemic area. In nonendemic areas, the diagnosis is often not considered unless a travel history is obtained.

The hematologic findings for primary coccidioidal infection consist of elevation of the erythrocyte sedimentation rate, leukocytosis, and sometimes, eosinophilia. Eosinophilia may be observed, but it occurs in a minority of patients.^{66,118} Hypercalcemia is occasionally diagnosed and is the result of aberrant production of parathyroid hormone–related peptide within coccidioidal granulomas.⁶⁵ Patients with coccidioidal infection may demonstrate cross-reactivity to the (1→3)-β-D-glucan assay, but the performance characteristics of this test in coccidioidomycosis cases are unknown.¹⁸⁸ Specific diagnosis is most often established serologically, but cultures, sputum examination, antigen testing, and histologic examination of tissue are often useful, particularly for immunocompromised patients, whose blunted antibody responses may yield false-negative serologic results.¹²⁵

Culture and Identification of the Fungus

The organism is detected readily by direct examination and culture from purulent material. The yield from other sources, such as pleural fluid, blood, and gastric aspirate, is somewhat lower. Approximately one third of CSF samples are culture positive, and direct examination of the CSF usually yields negative results.^{105,147} Detection of the fungus from the blood is an uncommon occurrence and is associated with severe forms of disseminated disease.⁴ Tissue biopsies of pleura, cavities, synovium, or meninges often yield the organism by culture or by histologic demonstration of coccidioidal spherules or hyphae.¹⁵⁹

In severe pulmonary or disseminated disease, microscopic examination of bronchoalveolar lavage specimens, exudates, or biopsy specimens is diagnostic if typical spherules containing endospores are seen. Hematoxylin and eosin–stained sections can be used to demonstrate spherules, but they are used mainly to show the inflammatory process. The periodic acid–Schiff stain is useful for demonstration of spherule contents (Fig. 201.9), whereas methenamine silver stains highlight the wall of the spherule. Potassium hydroxide stains are useful but lack sensitivity and specificity; calcofluor white fluorescent stains are more sensitive but require experienced technologists.¹⁴⁷ Cytologic examination of sputum is more sensitive than potassium hydroxide stains.¹⁸¹

Cytologic examination of bronchial wash or bronchoalveolar fluid is diagnostic for approximately one third of people with or without HIV infection and is less sensitive than culture.⁵⁷ The Gram stain is not useful because it is not picked up by the spherules.

FIG. 201.9 A recently ruptured spherule is in the process of releasing endospores.

With the rare exception of individuals with primary cutaneous infection, the finding of spherules in tissues outside the thoracic cavity is evidence that the patient has disseminated disease. Biopsy may be useful to establish a diagnosis, particularly for patients with negative or low complement fixation antibody titers. Cultures of *Coccidioides* spp. from body fluids, sputum, or exudates can be performed on most laboratory media. If coccidioidomycosis is suspected, the use of mycologic media containing cycloheximide can be helpful.^{101,164} The organism grows on routine bacterial, fungal, and *Legionella* media. Aerosolization of the organism is hazardous when handling cultures, and the use of biosafety level 3 practices is required. *Coccidioides* spp. are no longer designated as *select agents* by the Centers for Disease Control and Prevention (i.e., they do not pose a severe threat to public, animal, or plant health).

After a nonpigmented mold is grown, definitive identification of the organism is done typically by the use of genus-specific genetic probes.¹³² The probes do not differentiate between *C. immitis* and *C. posadasii*, and it is not clinically relevant to differentiate the two species. Real-time polymerase chain reaction assays are being developed for rapid detection of *Coccidioides* spp. in a variety of clinical specimens but are not commercially available.^{15,129}

Skin Test

Intradermal skin tests using lysates of the mycelial phase (i.e., coccidioidin) or the spherule phase (i.e., spherulin) have been used to elicit delayed-type hypersensitivity. Spherulin, unavailable since the late-1990s, was reintroduced in 2014.^{1,179} Skin test conversion typically occurs by the first week after onset of symptoms in 83% of healthy subjects and in 99% by the third week.

Skin test reactions may be negative for immunocompromised individuals and those with disseminated disease, and false positives have been reported due to hypersensitivity to the preservative thimerosal, which has been replaced with phenol in the newer formulation. Skin tests have primarily been used as epidemiologic tools or to monitor for the development of a cellular immune response by delayed-type hypersensitivity in anergic patients with disseminated infection.

Serologic Studies

The initial antibody response to coccidioidal infection is predominantly in the immunoglobulin M (IgM) fraction and is responsible for the positive precipitin test result that accompanies primary infection. Samples from 50% of patients yield positive results in the first week, and 90% do so within 2 to 3 weeks. Thereafter, antibody reversion occurs, and by 5 months, only 10% of patients with uncomplicated infection remain positive for IgM.¹⁵⁷ In contrast to immunoglobulin G (IgG) titers measured by complement fixation, the magnitude of the IgM titer does not correlate with an increased risk of dissemination.¹⁵⁶ IgM may persist in some patients with disseminated infection or may reappear with reactivation of infection. IgM occasionally has been detected in the cord blood of newborns whose mothers had detectable antibody, but these infants had no evidence of infection on follow-up.¹³⁴

IgM responses can be measured by tube precipitins, latex agglutination, enzyme immunoassay (EIA), or immunodiffusion methods.¹³⁴ Precipitating IgM antibody detected by the tube precipitin assay or by immunodiffusion usually indicates acute infection.¹⁵⁷ Latex agglutination is sensitive, rapid, and easy to perform but frequently yields false-positive reactions.¹³⁴ Positive results should therefore be confirmed by a second method. Latex agglutination produces false-positive results for CSF samples and diluted sera and should not be used for these specimens.¹³⁴

The EIA is a rapid method for the detection of IgM. It does not suffer from the subjectivity required to interpret the other assays, is less labor intensive, and may be positive earlier in the course of illness than other methods.^{70,104,122,183} Its reported sensitivity is 74%, but its initial reported specificity of 96% has been the subject of controversy, particularly in the absence of IgG positivity. Kuberski and colleagues found that 82% of patients with a positive IgM response and a negative IgG response had no evidence of coccidioidomycosis.¹⁰⁹ However, Blair and Currier detected few false-positive results among 706 EIAs, including 28 isolated IgM seropositives.²⁰ In a follow-up study of 1117 patients, of whom 102 patients (9%) had isolated IgM EIA positivity, IgM specificity ranged from 90% for the 60 patients with compatible

symptoms to 45% for the 29 asymptomatic patients undergoing screening.²² In Puerto Rico, which is not endemic for *Coccidioides* spp., isolated IgM positivity by EIA was observed in 1.5% to 3.4% of 534 samples (depending on the assay manufacturer), all of which were antibody negative for *Histoplasma*. Rates from 1218 samples from asymptomatic blood donors in Arizona were between 1.1% and 2.4%, suggesting that a proportion are falsely positive.¹¹⁴

Antibodies measured by complement fixation are slower to develop and primarily are in the IgG fraction.¹³⁴ They usually are not detected in serum samples obtained during the first week of illness, may appear as late as 3 months after onset of symptoms,^{96,157} and typically last 6 to 8 months.¹³⁴ Early therapy with fluconazole may interfere with the development of IgG antibodies.¹⁶⁵ The antibodies are seen more commonly in symptomatic infections and are detected in 50% to 90% of patients by 3 months after the onset of symptoms. At least 90% of people show a positive IgM or IgG response after symptomatic primary infections.^{134,147} The main methods of detection of IgG antibodies are complement fixation, quantitative immunodiffusion, and enzyme immunoassay.^{122,134,182,189} These assays correlate well, and immunodiffusion is particularly useful for detection of antibody in patients whose sera are anticomplementary.¹³⁴

The magnitude of the IgG titer correlates closely with the severity of infection and the likelihood of dissemination.¹⁵⁷ Although the antibody titer cannot be used as the sole indicator of dissemination, titers of 1:32 or greater in most laboratories strongly suggest extrapulmonary spread of infection^{95,157}; 61% of these patients have a titer of at least 1:16, whereas 95% to 100% of those without dissemination have a titer lower than 1:16. The titer of complement fixation antibody parallels disease activity and is useful in following the progress of patients with disseminated disease. A few patients, especially those with extensive pulmonary involvement and pleural effusion, develop high titers without other clinical evidence of dissemination.¹³⁴ Conversely, some patients with dissemination, particularly those with single lesions in skin, bone, or meninges, have lower titers. These antibodies are measured by complement fixation or immunodiffusion.

The IgG enzyme immunoassay has a sensitivity of 92% and specificity of 97%. The assay is qualitative. Unlike complement fixation titers, reported optical density or EIA index values have no prognostic or therapeutic significance. The complement fixation antibody is detectable in the CSF of 70% of patients at the time of diagnosis of coccidioidal meningitis and eventually becomes detectable in almost all. The antibody measured is not a reflection of serum levels but rather indicates specific immunoglobulin biosynthesis by cells residing within or contiguous with the central nervous system (CNS). Some patients with vertebral osteomyelitis or epidural abscesses produce low complement fixation titers in the CSF without other evidence of meningeal involvement.¹³⁴ Some patients with immunodeficiency disease, in particular HIV infection, can have extensive disease with low or undetectable antibody levels.^{2,134} Bone marrow transplant recipients may have no serologic or skin test response before or shortly after bone marrow transplantation, and aggressive attempts may be required to culture the fungus for diagnosis.¹⁴¹

Antigen Detection

Antigen detection assays have been developed for identification of *Coccidioides* galactomannan in urine, blood, respiratory secretions, and CSF.³ On the basis of preliminary data, they have detection rates of 50% to 71% for antigenuria and up to 73% for antigenemia when the specimen is treated with heat in the presence of EDTA to dissociate immune complexes.⁵⁹ Antigen cross-reactivity was observed in patients with histoplasmosis.¹¹⁰ A retrospective review of CSF coccidioidal antigen testing for 36 patients with coccidioidal meningitis revealed a sensitivity of 93% and specificity of 100%.^{3,103} Sensitivity of CSF antibody detection by immunodiffusion or complement fixation alone was 67% to 70%.

TREATMENT

Primary Infection

In more than 90% of children, primary coccidioidomycosis is a self-limited illness, and antifungal therapy is not needed. In some children with severe primary disease, therapy with antifungals may be justified

to abbreviate the period of morbidity or to lessen the chance of dissemination in those with an elevated complement fixation titer.

Whether patients with primary uncomplicated pulmonary infections should receive therapy remains controversial. When treatment is prescribed, the agent of choice is fluconazole, which is usually administered for 3 to 6 months. Evidence of severe infection or of concurrent risk factors such as immunosuppression should lead to the initiation of therapy. In adults, severe infections usually are heralded by weight loss of more than 10%, intense night sweats for a duration of longer than 3 weeks, infiltrates involving more than one half of one lung or portions of both lungs, prominent or persistent hilar adenopathy, complement fixation titers greater than 1:16, failure to develop normal skin test hypersensitivity to coccidioidal antigens, inability to work, or symptoms that persist for longer than 2 months.⁷⁵ Convalescence usually is prolonged with or without antifungal therapy.¹⁹

Diagnosis of primary coccidioidomycosis during the third trimester of pregnancy or immediately after delivery should prompt consideration of treatment. Amphotericin B is recommended for pregnant women in the first trimester because of the teratogenic potential of fluconazole, which is classified as a class D agent.¹² Thereafter, an azole antifungal or amphotericin B can be used. Fluconazole can be used in breastfeeding women, but other azoles should be avoided.¹²

Because of the high risk for dissemination, persons of African or Filipino ancestry should be considered for antifungal therapy. Immunocompromised patients, such as those with AIDS, recipients of solid organ transplants, patients receiving high-dose steroids, or those receiving TNF- α inhibitors, also warrant treatment.

When reticulonodular or miliary disease is seen, a more aggressive approach is warranted. Therapy usually is initiated with amphotericin B or high-dose fluconazole. Amphotericin B seems to yield a faster response and can be replaced by an azole after a few weeks.⁷⁵ The total course of therapy should last for at least 1 year and should be followed by oral azole therapy for secondary prophylaxis.⁷⁵

Asymptomatic pulmonary cavities usually do not require therapy. Consideration should be given to excision of some cavities that persist for longer than 2 years, are progressively enlarging, or are adjacent to the pleural cavity. For patients with cavities that result in local discomfort, superinfection, or hemoptysis, therapy with oral azoles may alleviate the symptoms. Resection of localized cavities is an alternative to recurrent courses of antifungal therapy.⁷⁵ Pyopneumothorax results from rupture of a cavity into the pleural space. Its treatment is surgical resection and decortication with or without a course of antifungal therapy. Chronic fibrocavitary disease usually is treated with oral azoles for at least a year. For patients with inadequate responses, increasing the dose of azole, switching to a different azole, and administering amphotericin B are options. Surgical resection may be helpful in cases of localized disease or when significant hemoptysis has occurred.⁷⁵

Asymptomatic pulmonary nodules resulting from coccidioidomycosis represent healed infection. They usually do not warrant therapy, except in immunocompromised patients.⁷⁵

Disseminated Disease

Nonmeningeal Dissemination

Patients with disseminated disease who have clinically apparent lesions outside the thoracic cavity typically require antifungal therapy, usually with an azole (i.e., fluconazole or itraconazole). In fulminant infections, amphotericin B is the agent of choice because it is thought to produce more rapid improvement.⁷⁵

The classic therapy consists of amphotericin B deoxycholate administered initially at a dose of 1 to 1.5 mg/kg per day and then tapered to 1 to 1.5 mg/kg per day three times per week. The usual duration of therapy is 3 months to 1 year. Local instillation or irrigation of abscesses and cavities with amphotericin B or other antifungal agents may be beneficial, but it has not been studied systematically.^{17,99} Total duration of therapy is determined by the patient's response. Lipid-complexed amphotericin B preparations offer the possibility of administering higher doses with less toxicity and have largely replaced intravenous amphotericin B deoxycholate.

The azoles have been tested extensively in this form of the disease. The main agents used are fluconazole and itraconazole. In a randomized,

double-blind study of progressive nonmeningeal coccidioidomycosis, a trend toward better efficacy with itraconazole, especially in the subgroup of patients with skeletal infections, was demonstrated.⁷⁷ For children, this approach must be weighed against the need for more frequent drug administration, dietary limitations related to the erratic absorption of itraconazole, and its higher cost. Itraconazole has important drug interactions, most notably with tacrolimus, cyclosporine, and phenytoin.⁸² Reports suggest that voriconazole and posaconazole offer effective treatment for patients refractory to fluconazole therapy.^{5,108,163} A single case report demonstrated beneficial results with the concurrent use of interferon- γ .¹¹¹

The azoles are used for several months after resolution of symptoms or for at least 1 year of therapy. Fluconazole should not be used in the first trimester of pregnancy because cases of multiple craniofacial and skeletal malformations somewhat reminiscent of the Antley-Bixler syndrome have been described.¹² The role of echinocandins is currently unclear.

Treatment is recommended for all HIV-infected individuals with active coccidioidomycosis and CD4 counts of less than 250 cells/ μ L. After the infection is controlled, discontinuation of the therapy is reasonable if the CD4 count has risen to more than 250 cells/ μ L, except in cases of meningitis, for which therapy should be lifelong.

Meningeal Disease

Fluconazole is considered the drug of choice for coccidioid meningitis.⁷⁵ Studies using 400 mg of fluconazole or itraconazole in the treatment of meningitis without concurrent use of amphotericin B have shown good results, with response rates of approximately 80%.^{76,168,169} Some experts prefer starting at a dose of 800 to 1200 mg of fluconazole or 600 mg of itraconazole.¹⁰⁰ On the basis of limited data, the pediatric dose of fluconazole is approximately 12 mg/kg per day.¹⁴⁵ Patients usually respond clinically within 1 to 2 months, although for some patients, abnormalities of the CSF may persist for a prolonged period. When therapy has been stopped, increases in CSF cell count or complement fixation antibody titer may be the only indications of reactivation of meningeal disease and signify a need to intensify therapy.⁵⁸

Before the availability of fluconazole, therapy with amphotericin B deoxycholate for coccidioid meningitis was associated with a marked improvement in survival rates.^{62,74} However, this requires prolonged intrathecal therapy through lumbar, ventricular, or cisternal administration. It is associated with significant side effects that include headache, nausea, vomiting, chills and fever, arachnoiditis, and occasionally, paralysis, seizures, and coma. The symptoms of arachnoiditis may be indistinguishable from those of microbiologic relapses.^{86,100} For these reasons, routine use of amphotericin B deoxycholate has largely been supplanted by fluconazole therapy. Some investigators use intra-CSF administration of amphotericin in conjunction with an azole to achieve a faster response.

Significant attention should be paid to CSF flow dynamics because most children with coccidioid meningitis develop obstructive hydrocephalus, which requires ventriculoperitoneal shunting and rarely a second shunt to drain a trapped fourth ventricle.^{86,150} A systemically administered drug such as fluconazole obviates the problems of impaired CSF flow when intrathecal or intraventricular therapy is used. Monitoring CSF pressure is important in assessing the timing of CSF shunting; persistent pressures above 200 mm H₂O herald the need for shunting.¹⁰⁰

Studies have indicated that the relapse rate after discontinuation of azole therapy is high. Of 14 persons treated for coccidioid meningitis with azoles (i.e., ketoconazole, itraconazole, or fluconazole) for periods ranging from 8 to 101 months, 11 (78%) had a relapse of disseminated coccidioidomycosis within 0.5 to 30 months after therapy was stopped. There were no clinical or laboratory predictors of patients at risk for relapse. The data indicate that moderately prolonged azole therapy for coccidioid meningitis suppresses but does not eradicate the infection, suggesting the need for prolonged or lifelong therapy.⁵⁵

The role of systemic corticosteroids in the management of coccidioid CNS infection, particularly in the setting of vasculitis, is an area of controversy. Some experienced practitioners advocate the use of a short course of high-dose dexamethasone with a rapid taper, analogous to

the regimen employed in tuberculous meningitis.¹¹² Whether this approach is beneficial or detrimental has not been studied systematically.

Surgical Management

Surgery seldom is required in patients with primary disease, but therapeutic thoracentesis may be indicated rarely when pneumonitis is complicated by large pleural effusions.¹¹ Surgery also is necessary when pericardial involvement is complicated by tamponade. Patients with persistent coccidioid cavities (>2 years) may require lobectomy, especially if the lesions are symptomatic.⁷⁵ Coccidioid lymphadenitis occasionally requires excision.

Bone and joint disease requires a combined surgical and medical approach. Coccidioid arthritis typically responds poorly to systemic therapy, and synovectomy may aid in the control of symptoms.^{17,18} Osteomyelitis optimally is dealt with by curettage and drainage of the involved bone, with the addition of amphotericin B therapy, itraconazole, or fluconazole.^{17,31,53,77} Itraconazole appears to be more effective than fluconazole in skeletal infections but not for other forms of the disease.⁷⁷ The role of neurosurgical intervention to relieve elevated intracranial pressure in CNS disease was discussed previously.

Refractory or Progressive Disease

A variety of alternative regimens have been successfully used as salvage therapy in refractory or progressive disease, but data remain limited to case reports and small case series, with various definitions of what constitutes treatment failure. Regimens have included monotherapy with liposomal amphotericin B, voriconazole, or posaconazole. Combinations with purported efficacy include voriconazole with caspofungin (i.e., nine patients, two of whom had CNS disease, and one who did not survive)¹²⁴ and liposomal amphotericin B with an azole, sometimes with the addition of caspofungin.¹¹³ The role of combination therapies in CNS infections has not been defined.^{46,108,138,148,163}

PROGNOSIS

Primary pulmonary coccidioid infection usually is self-limited, with complete recovery occurring as early as 1 to 3 weeks after starting treatment, but it often results in prolonged convalescence. Fatigue, sometimes severe, is commonly seen in individuals with symptomatic coccidioidomycosis.²⁴ A prospective cohort of healthy adults with mild to moderate primary disease reported an average time to complete resolution of symptoms of 4 months regardless of whether antifungals were prescribed.¹⁹ In a few cases, localized complications of the primary infection, such as pleural effusion or pericarditis, prolong the clinical course.

Dissemination is a rare event among whites and is less likely to occur in patients with erythema nodosum. Until the late 1950s, no effective therapy was available for the more severe forms of coccidioidomycosis, and the mortality rate for patients with disseminated disease was approximately 50%.⁶⁶ The mortality rate for patients with multiple sites of dissemination and those with coccidioid meningitis approached 100%. Current therapy with amphotericin B or azoles may cure some of these patients, and it prolongs useful life for many others.

Certain forms of disseminated infection, such as synovitis, are resistant to systemic therapy and may persist for many years without other signs of dissemination. For patients with HIV infection, therapy for disseminated coccidioidomycosis usually is not curative, and lifelong suppressive therapy with intermittent doses of amphotericin B or oral azoles may be required to prevent relapses in those with CD4 counts less than 250 cells/ μ L. Those with counts higher than 250 cells/ μ L have a clinical course that is similar to that of immunocompetent individuals.¹²³

The prognosis for pregnant women has markedly improved with antifungal therapy.¹² The azoles are a major advance in the therapy for coccidioid meningitis, although they are fungistatic and require lifelong administration, sometimes failing to maintain remission of disease. Solid organ transplant recipients remain at risk for disseminated disease and increased mortality rates due to primary or reactivation disease when coccidioidomycosis develops after transplantation.

PREVENTION

Prevention of primary coccidioidal infection with antifungal agents or physical barriers such as masking is not practical. In endemic areas, control of dust, avoidance of wind storms, and avoidance of soil digging can decrease the risk of infection. Vaccine efforts are continuing but have not yielded a viable candidate vaccine.

Within endemic areas, routine serologic screening and primary prophylaxis are not indicated for HIV-infected children³⁷ and those receiving TNF- α inhibitors.⁷⁵ Azoles have been used for primary and secondary prophylaxis in endemic areas for patients with solid organ transplants. Because of inhibition of the cytochrome P450 system, levels of cyclosporine and tacrolimus should be monitored.²¹ The duration of primary prophylaxis usually is 6 to 12 months or more after transplantation, but the optimal dose and duration are unknown. For secondary prophylaxis in immunocompromised individuals, azoles are continued for the duration of immunosuppression due to a high risk of reactivation disease.⁷⁵

Paracoccidioidomycosis

Gil Benard • Maria José Soares Mendes-Giannini

Paracoccidioidomycosis, formerly known as South American blastomycosis, caused by *Paracoccidioides brasiliensis* and *Paracoccidioides lutzii*, is usually a progressive chronic disease that preferentially affects the lungs, skin, mucous membranes, adrenals, and reticuloendothelial system. Benign, self-limited infections also have been occasionally documented. Two types of clinical presentations are described: the acute-subacute (juvenile) and the chronic (adult) forms of the disease.¹⁰¹ The prevalence of the disease is limited to the American

continent, from Mexico to Argentina. The differences between the clinical forms may be related to multiple factors, among them, deforestation at agricultural frontiers, as occurs in some Brazil regions. Occupational exposure of children and young adults to different species of *Paracoccidioides* during agricultural work may be larger at these places.⁹²

Children generally present with the acute form, which affects predominantly the reticuloendothelial system organs. Children account

for about 5% to 10% of cases, and both sexes are infected⁴; the systemic form of paracoccidioidomycosis occurs in about 70% of episodes.^{24,29,136,154,184} The disease is acquired by soil aerosolization and inhaling of infectious particles of *Paracoccidioides* spp.^{40,100} The mycosis is limited geographically to various Latin American countries[†], but some cases of paracoccidioidomycosis have been reported and diagnosed in countries outside Latin America.^{40,43,57,118,127,133} This disease may be considered a traveler's disease in this condition²⁰⁰ and now is included among the neglected diseases.¹¹⁹

The disease was described originally by Lutz in Brazil in 1908 and initially observed in children in 1911.¹²⁸

ORGANISM

The *Paracoccidioides* genus consists of dimorphic fungi, the etiologic agents of paracoccidioidomycosis. Currently, phylogenetic studies divide the *Paracoccidioides* genus in two species, named *Paracoccidioides brasiliensis* (S1, PS2, PS3, and PS4 phylogenetic species) and *P. lutzii* (Pb01-like).^{149,247,171,252}

The recognition of *Paracoccidioides* spp. as an anamorph in the phylum Ascomycota, order Onygenales, family Ajellomycetaceae has been accomplished by means of molecular tools.^{28,261} *Paracoccidioides* spp. are phylogenetically closer to *Lacazia loboi* than to *Blastomyces dermatitidis*, *Emmonsia parva*, and *Histoplasma capsulatum*.²⁶¹

The fungus has four or five DNA chromosomes showing molecular sizes ranging from 2 to 10 Mb.^{50,93,164} The genomes range in size from 29.1 to 32.9 Mb and encode 7610 to 9132 genes,^{1,82} which is in agreement with the estimated gene number for ascomycete fungi genomes. Genomic analysis of *P. brasiliensis* and *P. lutzii* pointed to important differences. Although the genome sizes of the two cryptic species (S1/Pb18 and PS2/Pb03) of *P. brasiliensis* are comparable (30 Mb and 29.1 Mb, respectively), the *P. lutzii* genome is almost 3 Mb larger (32.9 Mb). The total number of initial predicted genes varies between 7875 in *P. brasiliensis* and 9132 in *P. lutzii*. Transposons may be one of the reasons for the widening of *P. lutzii* genome because they constitute 16% of it, twice as much as that of *P. brasiliensis* S1/Pb18 and PS2/Pb03 genomes (8–9%).⁸²

Differences between *P. lutzii* and *P. brasiliensis* (S1, PS2, and PS3 species) were also observed in their proteomic yeast profiles by means of two-dimensional electrophoresis and mass spectrometry. The expression levels of the enzymes related to glycolysis suggested the use of a more anaerobic metabolism for energy production from glucose in the *P. lutzii* (Pb01 isolate).¹⁹⁵

Paracoccidioides spp. genome information is available at: http://www.broad.mit.edu/annotation/genome/paracoccidioides_brasiliensis.

Paracoccidioides spp., a thermally dimorphic fungus, appears as round to oval yeast cells of variable size (6–40 µm) in tissues and culture at 37°C, and in the environment or in vitro at temperatures lower than 24°C it changes its morphology to the mold form when cultured under starvation conditions in minimal media. Conidia and mycelial fragments are considered the infectious particles. When inhaled, they reach the alveoli, where, at the host tissue's temperature (37°C), they change from their saprophytic form to the parasitic multiple budding yeast form capable of producing disease.^{128,198,199} Another important fact is that *P. brasiliensis* is able to form biofilm in vitro, which opens up new possibilities in understanding the infection process of these fungi^{53,77} because biofilm formation is a condition that provides for the pathogen's protection against drugs and the host's immune system.²²⁷

Different groups have addressed the overall scenario of gene expression in *Paracoccidioides* spp. yeast versus mycelium, or undergoing phase transition in vitro, making use of different molecular methods.^{14,94,108,117,126,138,179,185} Many genes were also described related to conidia,¹¹⁶ in the parasitic phase in vitro^{37,70,236} as well as in vivo models of infection.^{10,9,70,88,111,134,151,159,160,178,194,237} Recently, this approach focused on identification of regulated transcripts analysis of *Paracoccidioides* spp. yeast cells treated with different drugs.⁶⁹

In the mycelial phase, growth is slow, requiring approximately 3 to 4 weeks; the colony is white to tan and compact, with short aerial

mycelia. On microscopic examination, hyphae are fine (0.8–2.5 µm in diameter), septate, interlaced, and hyaline. Chlamydoconidia (20–50 µm in diameter) that are round to subspherical, terminal, and intercalary, as well as arthroconidia, may be observed.^{128,206,234} Some isolates can produce aleurioconidia, uninucleate pear-shaped pedunculated or terminal structures, after long periods of incubation and under nutritional deprivation (media with reduced carbohydrate content).^{40,128,210} The small size of these conidia (<5 µm) renders them compatible with alveolar deposition; furthermore, such conidia have been shown to be infectious when they are inhaled.¹⁵²

The mycelial phase is not distinctive, and subcultures at 37°C are required for complete identification. At this temperature, *P. brasiliensis* produces soft, wrinkled, cream-colored colonies that develop in approximately 6 to 10 days. On microscopic examination, the most characteristic feature is the presence of multiple budding yeast cells; the parental cell produces various peripheral buds and acquires the appearance of a pilot's wheel. *P. brasiliensis* may possess alternative control mechanisms during cell growth to manage multiple budding and its multinucleate nature.¹ Single buds and short chains also are produced, but they are not diagnostic. Cells are variable in size (2–40 µm) and have a thick cell wall and internal vacuoles.^{40,199} Differences in daughter cells were observed in relation to the two species,^{240,247,248,252} as well as in sporulation (concerning conidia amount and morphology) among the different cryptic species: S1 isolates produce a higher conidia amount compared with other *P. brasiliensis* and *P. lutzii*. The growth is identical to the one observed in tissue and pathologic materials.^{40,102,128,199,206} The organism does not readily take most bacterial or hematologic stains. *P. brasiliensis* is aerobic, but to form biofilm in vitro it needs hypoxic conditions.²²⁷ The fungus in mycelial phase grows well in the regular mycologic media to which antibiotics and cycloheximide have been added to reduce growth of bacteria and saprophytic fungi. Isolation should be attempted by the use of modified Sabouraud agar, yeast extract (15%) agar plus antibiotics and cycloheximide, yeast extract–phosphate agar, brain-heart infusion agar plus blood and antibiotics, or tryptic soy agar plus fungus water extract and horse serum, incubated at room temperature.^{40,128}

TRANSMISSION

Paracoccidioidomycosis is not a contagious disease.^{40,102,128,206,267} A single case of placental involvement that did not result in fetal infection has been reported.³² Epidemic outbreaks have not been reported, and only a few cases in family members have been documented,^{128,130,267} which could be attributed to the long periods of mycosis latency between the moment of infection and the appearance of overt clinical manifestations.²⁰⁵ Consequently, the patient's memory of the activity contributing to the infection or of the accompanying individuals usually has been forgotten, which prompted Borelli³⁶ to coin the name “reservarea” for those places in the endemic areas where the fungus has its habitat and humans acquire the infection.²⁰⁹ This concept differs from that of an endemic area, which implicates the place where the disease is diagnosed.

P. brasiliensis infection in animals as proved by culture or histologic examination has been shown consistently in armadillos, mammals that probably acquire the infection when they disturb the terrestrial habitat of the fungus.^{7,45,204,215,238,249} and more recently in a dog.^{74,212} The spatial distribution of the pathogens has been done by molecular detection from soil^{4,86,239,267} and by their isolation from wild animals such as armadillos.^{4,63,238} This approach is important for monitoring their environmental and geographical distribution.⁴

Unfortunately, the microniche of *P. brasiliensis* has not been identified properly; soil has been incriminated, but the number of isolates from this source is small.^{204,251,267} The inhibitory effect of pesticides on *P. brasiliensis* may suggest that they can interfere with attempts to isolate *P. brasiliensis* from soil.¹⁸¹ Recently, the role played by deforestation in increasing both exposure and incidence rates has been documented in Brazil in Amerindians and in children.^{59,98,148,215}

Some studies are developed related to presence of the fungus in environmental aerosol samples² and related to climate change.^{13,12} Species-specific inner primers derived from rDNA regions (internal transcribed spacer [ITS], 5.8S gene) have been described, and the nested

*References 11, 22, 25, 55, 86, 96, 98, 112, 115, 130, 173.

†References 7, 16, 33, 36, 40, 41, 43, 61, 128, 144, 184, 204, 234.

polymerase chain reaction (PCR) sensitivity was higher for the detection of *P. brasiliensis* in soil than in culture and animal inoculation. The fungus was detected in soil artificially seeded (positive soil control) and from environmental samples collected in an armadillo burrow.²⁵¹ This approach probably would improve the fungal microniche studies. *P. brasiliensis* S1 and PS2 species (São Paulo state, Brazil) and PS3 (Colombia) have been highly recovered from the armadillos *Dasypus novemcinctus* and *Cabassous centralis* in endemic areas, whereas no *P. lutzii* has been isolated from these animals yet.⁴

The ecologic factors that prevail in the reservarea also have been characterized, with the following being significantly associated with the disease: altitude 1000 to 1499 m above sea level, annual rainfall 2000 to 2999 mm, and presence of humid forests and of coffee and tobacco crops.⁴⁷ Environmental correlates (soil texture and precipitation) indicate that moisture availability plays an important role in paracoccidioidomycosis distribution.²³⁹ The fertile regions of endemic areas have the highest incidence rates of paracoccidioidomycosis.^{47,144,256}

Paracoccidioidomycosis was thought, and still is by some, to be acquired by trauma. However, clinical and experimental data indicate that infection is acquired most commonly by inhalation.^{40,112,130,211}

EPIDEMIOLOGY

Paracoccidioidomycosis is a fungal diseases with high medical and social impact in areas of high endemicity because of the considerable number of cases, chronicity of the disease, treatment, and frequent sequelae that cause inability to work and poor quality of life. The epidemiology of this disease has some difficulties because of the noncompulsory notification, the difficulty in recognizing the recently acquired infection, and the absence of epidemic outbreaks.

INCIDENCE

The incidence of paracoccidioidomycosis was estimated at 0.71 to 9.40 per 100,000 inhabitants per year, depending on the region.^{16,40,55,144} Some South America countries have a lower incidence of paracoccidioidomycosis, with the exception of Brazil and Colombia.⁶¹ The incidence of the mycosis may temporarily reach higher rates in areas with major socioenvironmental changes.

Age

Patients with paracoccidioidomycosis vary in age from 2 to more than 80 years.^{11,16,33,52,55,128,130,267} The prevalence is higher (>70%) in patients who are 30 years or older. The number of childhood cases was shown to vary from 2.1% to 12.7% in the first decade of life, depending on the region.^{16,33,55,98,130,184} These series, some compilations,^{25,177,191,189} several individual reports, and a thesis¹¹ have revealed that the disease occurs more frequently in individuals 12 to 15 years of age than in younger children (Table 202.1). More than 250 reports of paracoccidioidomycosis in children aged 3 to 14 years, including those analyzed by Londero and colleagues¹³⁰ have been found in a literature search. Bellissimo-Rodrigues and colleagues¹⁶ described 1219 patients, among whom 196 (16%) were younger than 21 years, and 42 (3.4%) were 3 to 10 years of age. Other studies reported incidence rates of 15.4% to 20% in the Midwest or Southeast regions of Brazil.^{33,184}

The intradermal application of *P. brasiliensis* antigens is used to measure delayed hypersensitivity and most frequently is used to detect

asymptomatic infection with the fungus. In certain places, the infection rates measured by a positive skin test reaction also were high. In 1976, Pedrosa¹⁸⁸ found that 34% of the children tested positive for paracoccidioidin, a figure indicative of early exposure to the fungus. The prevalence of infection with *P. brasiliensis* was evaluated in a cross-sectional study of 298 asymptomatic schoolchildren in the Brazilian Amazon region. The skin test reactivity of children was 4.6% to two different *P. brasiliensis* antigen preparations, paracoccidioidin and a purified 43-kDa glycoprotein (gp43).¹²³

The relative paucity of children with this mycosis in comparison with the figures reported in adults^{40,128,267} may be explained, in part, by the effective control exerted by most hosts on the progression of the primary infection, by the long incubation period characteristic of the mycosis, and by the establishment of latent foci that may become apparent clinically many years after initial exposure.^{20,40,101,106,205,267}

Benard and associates²² consider that the association with different age groups is related to the epidemiology of paracoccidioidomycosis because in the endemic areas, as previously shown, children become exposed to the fungus at an early age. In healthy children, appropriate defenses usually curtail development of the mycosis, but in infants of low socioeconomic conditions, the transition from infection to overt disease may be accelerated and aggravated by the mycosis itself, by malnutrition, or by other associated conditions.^{17,24,25,33,106,216} In addition, unknown susceptibility factors, the intensity of exposure to the infectious source, the virulence of certain isolates, and other factors may well contribute to the development of the disease in children.^{20,60,97,98,114,130,267} The reduction in acute-subacute cases observed in the recent descriptions may be related to the lower exposure of children and adolescents to the fungus as a result of the intense public policy aimed at reducing child labor in agriculture.⁹²

Gender

Adult men are afflicted with much greater frequency than are women, but the male-to-female ratio varies according to geographic region.^{33,40,98,155,174} In children, however, the disease affects boys and girls in approximately equal proportions.^{33,47,55,130,176,215,267} (see Table 202.1). These findings suggest that sex hormones, hormone-dependent immunologic factors, or both play a role in determining the outcome of the host-parasite interaction.^{6,5,40} Researchers have shown in vitro that estrogens inhibit *Paracoccidioides* mycelium to yeast transition, thereby hindering the progression of the infection.^{6,228} Analysis of the mortality profile from paracoccidioidomycosis according to gender and age showed similar death totals for both genders in the groups younger than 20 years. The majority of deaths among male patients (97.14%) occurred in individuals older than 15 years, with only 2.37% among individuals younger than 15 years. Among female patients, most deaths from paracoccidioidomycosis (89.21%) also occurred in those older than 15 years, but 9.75% did occur in those younger than 15 years; that rate is nearly 5 times the percentage observed in males. These findings corroborate the literature, according to which the infection and disease occur equally between the genders during childhood, with a slight predominance of males with the disease, compared with an absolute predominance of males among adults with the chronic form of the mycosis.⁶⁵

Occupation and Race

Almost half of the reported cases in adults occur in individuals whose occupations require extensive exposure to the soil. Adult residents of areas in which paracoccidioidomycosis is endemic generally develop disease less severe than that seen in immigrants or in people who migrate to highly endemic settings. These people often develop disseminated infection, much like the juvenile cases do. The proportion of acute-subacute cases observed in the Bellissimo-Rodrigues study¹⁶ (26.4%) might be explained by the higher proportion of children, women, and African descendants. The influence of genetic traits on the mycosis has not been elucidated,⁸⁴ but in patients with the unifocal chronic form of the disease, a mild clinical presentation in which lesions are restricted or localized, the HLA allele most commonly seen was DRB1*11, suggesting that the participation of HLA antigens may influence the outcome of the host-parasite interaction in paracoccidioidomycosis.²²²

TABLE 202.1 Age and Gender Distribution in 354 Children With Paracoccidioidomycosis			
Gender ^a	AGE		Total by Gender (%)
	3–9 y	10–14 y	
Male	95	125	220
Female	63	71	134
Total by age	158 (41.8%)	196 (58.2%)	354 (100%)

^aMale-to-female ratio = 1.6:1.

Geographic Distribution

Paracoccidioidomycosis is restricted to Latin America, from Mexico to Argentina; some countries within this area (Chile and some of the Caribbean Islands), however, are free of the disease. In endemic countries, the disease distribution is uneven, and most cases occur in individuals living in regions corresponding to the humid tropical and subtropical forests. The endemic area is centered in Brazil (80% of the reported cases), followed by Venezuela, Colombia, Ecuador, and Argentina.^{33,128,130,141,267} New endemic areas have been reported in the Amazon region, where the mycosis was considered to be rare. In Brazil, this fungal infection is considered to be a very important cause of mortality among infectious diseases, with a rate of 1.45 cases per 1 million inhabitants.^{31,65,141,148} Paracoccidioidomycosis represented the most important cause of deaths among systemic mycoses^{65,196} (approximately 51.2%).

Although paracoccidioidomycosis has been reported in patients not living in endemic areas, prior residence in Latin America has been documented in every case.^{43,45,118,124,133,239} In some of these patients, the interval between residence in the endemic area and clinical manifestations of the disease has been 10 to 40 years.^{43,128} Within endemic areas, 2% (among children) to 82%, react to the intradermal administration of paracoccidioidin, suggesting previous contact or subclinical infection with *P. brasiliensis*.^{40,45,59,61,123} Even though the mycosis is powerfully related to the rural environment, cases of paracoccidioidomycosis acquired in suburban areas have also been described.

P. brasiliensis is a complex species,^{149,150} and phylogenetic studies have revealed that this species actually contains at least five cryptic phylogenetic species.^{247,248} *P. brasiliensis* S1 is associated with most paracoccidioidomycosis cases and is widely distributed in South America by means of armadillos, soil, and penguin feces. Recently, S1 lineage was separated into two clades (S1a and S1b); S1b presented high recombination, and all of the S1b strains are clinical isolates and include virulent strains, although not differentiate clinical forms.¹⁷¹ PS2 comprises a paraphyletic and recombining population that has been identified so far only in Brazil and Venezuela; PS3 comprises a monophyletic and clonal population that has been recovered in humans and armadillos in endemic regions of Colombia; and PS4 was recently identified and is composed of a monophyletic population of clinical isolates from Venezuela.^{4,149,150,214,247,248,224,250} *P. lutzi* comprises a single monophyletic and recombining population found to date in central, southwest, and northern Brazil and Ecuador. Despite the apparently restricted ecologic niche, the habitat of the etiologic agent has not been determined precisely.^{4,100,171,204}

PATHOGENESIS AND PATHOLOGY

The initial stages of the host-parasite interaction are unknown because of our inability to detect the precise moment when infection does occur.¹⁷ However, through the study of many cases, including autopsies, what has become apparent is that pulmonary lesions are primary, with the infection taking place by inhalation of fungal propagules.^{22,106,208} In experimental animals, the inhalatory route has been shown to give rise to disseminated disease.¹⁵² In most cases, the initial pulmonary infection does not cause undue symptoms.^{101,130} When the conidia reach the terminal bronchi or the alveolar spaces, yeast transformation ensues.¹⁵² In some cases, the fungus promptly disseminates by the lymphohematogenous route, producing distant subclinical and quiescent foci. Apparently, the local defenses are capable of controlling fungal spread, but some viable yeast cells may remain dormant in such foci, most commonly in the pulmonary and mediastinal lymph nodes, and eventually in other organs.^{41,23} Rarely, the initial pulmonary infection outweighs the host's immune defenses, causing an acute-subacute disease, the juvenile type, with predominant involvement of the reticuloendothelial system.^{64,101} The disease in children falls into this category. Often, the quiescent foci remain so throughout life, as demonstrated by the high number of subclinical infections compared with the low disease incidence of this mycosis in the endemic regions.^{99,267} Nevertheless, the most common clinical presentation of the disease is the chronic form, or adult-type disease, believed to result from fungal reactivation

FIG. 202.1 An 11-year-old boy with a 5-month history of fever and cervical and axillary lymph node enlargement, with fistulization.

in these foci.¹⁰¹ This reactivation frequently occurs when the patient has left the endemic area, as demonstrated by the cases reported outside Latin America, in countries where paracoccidioidomycosis is considered an imported pathology.³⁷ Of note, these cases may manifest decades after leaving the endemic area, leading to difficult and delayed diagnosis.¹¹⁸

Thus, in the acute-subacute form, the initial lung infection may pass unnoticed but is followed by prompt dissemination to other organs and tissues.²² In the chronic form, lung pathology frequently occurs. Pathology is restricted to the lungs in some of these patients, but in most, other organs also are afflicted. This may be caused by lymphohematogenous dissemination from reactivated pulmonary foci or directly from foci at virtually any organ.^{23,41} Actually, paracoccidioidomycosis, in the acute-subacute or chronic forms, is more frequently a disseminated disease, even though clinical manifestations may appear to be restricted to a sole organ.^{101,269} However, determination of the degree of dissemination certainly is influenced by the availability of diagnostic procedures. After appropriate therapy, residual lesions, mostly fibrotic, become established in a nonnegligible number of patients and represent the actual main challenge in this disease.^{64,102,154}

As already mentioned, the disease in children is acute-subacute and progressive (the juvenile form).^{25,55,130} The time that elapses between infection and the onset of symptoms is not known precisely but has been estimated to be short in most cases, such as a few months according to the rare case reports with putative known date of infection.^{41,101} The juvenile form is usually a severe, systemic disorder that involves preferentially the reticuloendothelial system (Fig. 202.1) to such an extent that it is the hallmark of the process.^{11,25,130}

In adults, pulmonary lesions as seen on chest plain films may be defined as micronodular or miliary, nodular, infiltrative or interstitial, cavitary, fibrotic, and mixed types.^{154,262} Emphysematous areas, pleural thickening, and enlarged hilar and mediastinal lymph nodes also can be observed. These alterations can be better visualized by computed tomography.^{103,241} Lung involvement probably is secondary to a chronic lymphangitic process provoked by the fungus itself and the host's response represented by formation of granulomas and fibrosis, the latter of which predominates at the perihilar region. This aspect correlates with the butterfly-like (perihilar) micronodular and interstitial infiltration observed on plain films.²⁶⁰ Obstruction and reversal of lymphatic flow would lead to the spread of the inflammatory process throughout the lungs.²⁶⁰

In children and adolescents, the pulmonary component tends to pass unnoticed, and neither clinical examination nor radiologic studies

reflect the real damage.¹⁰⁶ Actually, only a minor proportion of the cases reported have included lung symptoms.^{130,210} However, lack of notification may be more apparent than reality because the weight of the extrapulmonary lesions tends to minimize the less intense respiratory manifestations. Frequently, the mycosis is misdiagnosed, especially for tuberculosis and certain lymphomatous disorders.¹³⁰ Nonetheless, a careful search of pulmonary samples, including induced sputum, may reveal the characteristic multiple-budding *P. brasiliensis* yeast cells.^{130,211} Moreover, gallium and computed tomography have allowed detection of incipient or discrete interstitial pulmonary lesions not revealed by plain radiographs.^{103,269}

Lesions in the oropharyngeal and laryngeal mucosa occur frequently in the chronic form. They may be infiltrative, ulcerated, nodular, or vegetative and usually have a granulomatous aspect and may mimic squamous cell carcinoma.^{29,154,161,226} The base of the ulcerated lesions usually is covered by small abscesses (the mulberry-like lesions) that probably represent fungal dissemination through the lymphatic system because they usually are accompanied by regional lymph node involvement.⁵⁴

In children, such mucosal lesions are rather exceptional, but skin involvement occurs more commonly and tends to be multiple, in contrast with the adult chronic form.¹⁵⁴ In the latter, lesions are represented mostly by contiguous involvement of the periorificial mucosal lesions or draining lymph nodes. In children or young adults, and eventually in adults with the chronic severe disseminated disease, they represent hematogenous spread of the fungus. In this case, the lesions may appear as ulcerated or ulcerovegetative lesions, papules, or crust-covered ulcers and warts, usually at the same stage of development. Skin involvement may rarely present as sarcoid-like lesions.^{60,173} Reports of septic shock caused by septicemia by *P. brasiliensis* show that the fungus can be bloodborne.¹¹⁵

The reticuloendothelial system is the target organ in both children and young adults.¹¹ Almost every child with paracoccidioidomycosis exhibits involvement of the superficial or deep lymph node chains. Lymph nodes vary in size, number, consistency, and location; with time, they may liquefy, forming abscesses or fistulas (Fig. 202.2). The spleen and liver frequently are involved in these same groups. Abdominal lymph node involvement also is a common occurrence in children.^{11,130} Hypertrophied lymph nodes, usually generalized but particularly periaortic, around the hepatic hilum and retroperitoneally, can be detected by ultrasonography (see Fig. 202.2), computed tomography, or magnetic resonance imaging.¹⁴⁵ Coalescent masses may become palpable and may result in pathology caused by extrinsic compression of adjacent structures, such as jaundice by compression of the biliary duct,³³ pancreatitis,³³ or an intestinal obstruction.¹⁴⁶

FIG. 202.2 Extensive mesenteric lymph node enlargement (L) in a 10-year-old boy as shown by ultrasonography imaging.

Splenic lesions are nodular or miliary. Gross hepatic lesions may not be apparent, but histopathologic examination regularly reveals fungal invasion of this organ.^{11,25,34,130} In a series of fatal cases of paracoccidioidomycosis, 56.7% revealed the presence of yeast cells in the liver, associated with a granulomatous tissue response. Thirty percent of the patients had only widening of the portal tracts by fibrosis (31.6%), whereas 11.6% had an essentially normal liver.²⁴⁶ Younger patients and those with severe hypoalbuminemia are more likely to present with liver involvement by *P. brasiliensis*.³⁹

The intestinal mucosa may be affected, but similar to the lungs, its involvement is secondary to blockade of the regional lymphatic flow, with retrograde progression of *Paracoccidioides* spp. to the mucosa, a process resulting in mycotic enteritis.^{33,97,146} In this case, the submucosal inflammatory process is granulomatous; fungal cells are visualized; and the intestinal changes may vary from dilated loops, edema, congestion, and nodule formation to multiple mucosal ulcers.^{97,146}

Studies also have shown bone marrow infiltration mainly, but not exclusively, in the acute-subacute form of the disease: in a small case series report, 25.7% of the patients examined during active disease and 36.4% of those who died of paracoccidioidomycosis revealed this type of involvement.²⁰² Bone marrow necrosis has also been reported in the juvenile form.²⁰³ The histology pattern was variable, but appropriate staining always displayed fungal cells. Bone marrow invasion frequently is associated with marked eosinophilia.^{202,232} In addition, bone (Fig. 202.3) and joint lesions are frequent occurrences in the acute-subacute form of the disease^{3,25,130,259} and appear closely related to bone marrow infiltration.²⁰²

The adrenals often are involved in patients with the chronic form of the mycosis, with a small proportion of the patients evolving to adrenal hypofunction or insufficiency (Addison disease). The glands contain multiple granulomatous foci, and diffuse necrosis may be seen in the most severe cases. Hyperplasia of the adrenal glands also occurs commonly.¹⁵⁴ Adrenal insufficiency has been documented in patients even after prolonged posttherapy follow up.²⁵⁴

Histologically, formation of granulomas is the rule, except in patients with severe disseminated disease such as those with the acute-subacute form.¹⁰² The granulomatous inflammation is associated with a mixed pyogenic component, especially in the case of ulcerated skin lesions or ruptured lymph nodes.¹⁸³ Caseation and central necrosis may be present. In compact granulomas, abundant epithelial cells, Langerhans or foreign-body giant cells, plasmacytes, and lymphocytes are seen; often, phagocytosis of the yeast cells can be observed. CD4⁺ lymphocytes dominate over CD8⁺ lymphocytes and appear as peripheral mantles around aggregates of macrophages and histiocytes.¹⁶⁸ In the juvenile disseminated disease, the inflammatory reaction is diffuse, with abundance of both mononuclear and yeast cells but sparse formation of compact granulomas.^{55,210} Loose granulomas appear unable to circumscribe fungal antigens, and at their periphery, *Paracoccidioides* spp. antigens may permeate throughout the intercellular space.²²⁵ Skin and mucous membrane lesions usually exhibit pseudoepitheliomatous hyperplasia and intraepithelial microabscesses.^{186,225} The role of neutrophils in the inflammatory response against *Paracoccidioides* spp. has recently been investigated, and it was shown that neutrophil extracellular traps are present in tegumentary lesions of patients.⁷⁹

An interesting aspect drawn from the previously described histologic studies is the frequent description of areas of extremely active disease characterized by pyogenic reaction and loose granulomas, rich in budding fungal cells, intermingled with areas with compact granulomas, rare fungal cells, and variable degrees of fibrosis. This mixed aspect can be observed in lymph nodes, skin, or pulmonary lesions, suggesting that the disease evolves through localized new bouts of fungal multiplication and tissue invasion, whereas the adjacent older lesions are on their way to fibrotic resolution. Computed tomography of the lung confirmed this aspect by depicting areas with alveolar condensation along with fibrotic and emphysematous zones and the simultaneous presence of features of more recent and chronic lesions.^{103,241}

Tissue reactions are nonspecific; thus diagnosis depends on finding *P. brasiliensis*. If the parasite is abundant, it may be identified by hematoxylin and eosin stains. Special fungal stains (e.g., Grocott silver methenamine), however, always should be employed, especially when

FIG. 202.3 Severe disseminated subacute paracoccidioidomycosis in a 9-year-old boy. (A) The chest radiograph shows mediastinal lymph node enlargement and mild bilateral infiltrates in the middle and lower fields. Osteolytic lesions of long bones: (B) humerus and (C) tibia and fibula bilaterally.

granulomas are examined. The typical multiple budding yeast cells must be found to establish a diagnosis. The presence of fungal cells of different sizes (2–40 μm) suggests the presence of *P. brasiliensis*. In some cases, short chains and cells with single buds also are observed, and in these patients, differentiation of *P. brasiliensis* from *Cryptococcus neoformans*, *Blastomyces dermatitidis*, and even *H. capsulatum* and *Pneumocystis jirovecii* must be made.^{40,235} When the disease is chronic, most of the fungal cells are found inside the macrophages, but free yeast cells predominate in disseminated cases. Internalized yeast cells exhibit altered morphology.²⁰⁵

Like other chronic granulomatous diseases, paracoccidioidomycosis is also phenotypically a spectral disease, with the acute-subacute form of the disease characterized by poor cellular immune responses; high fungal burden; high anti-*Paracoccidioides* antibody titers, including those of the immunoglobulin E (IgE) subclass; and eosinophilia—all of which are typical of a predominance of helper T-cell subtype 2 (Th2) over Th1 immune responses.¹⁷ Conversely, some patients with the chronic form have a localized disease, low fungal burden, compact granulomas, and low antibody titers, suggesting that they are still able to mount Th1 responses. The latter patients would eventually have a specific “protective” genetic background.²²² In between would stay the chronic multifocal patients with deficient Th1 responses without marked shift to Th2 responses.¹⁷ However, the simplistic view of a Th1/Th2 paradigm of immune response has been complicated further by the description of new subtypes of helper T cells such as Th17 cells, Th9 cells, and Th22 cells. The clinical phenotypes presented by these patients have recently been associated with these subsets, and in the acute-subacute form a mixed Th2/Th9 response was detected predominantly, whereas in the chronic form there was a balance between Th1, Th17, and Th22 responses depending on the extent of the disease.⁷³

CLINICAL MANIFESTATIONS

Paracoccidioidomycosis is a polymorphic disorder that at a particular time may involve more than one organ system (Table 202.2). Thus, making a topographic classification is unrealistic, and the classification of the mycosis currently accepted takes into consideration not only the

TABLE 202.2 Clinical Findings on Admission Diagnosis in Children With Paracoccidioidomycosis

Clinical Findings	No. of Children (%) ^a
Lymph node enlargement	
Superficial	81.6

Pleural effusion	5.1
Oral and upper respiratory tract mucosa lesions	9.2

^aTotal number of children investigated for each clinical finding varied from 98 to 199. Data from references 3, 16, 60, 89, 98, 133, 162, 176, 189, 208.

organs involved but also the host’s immune condition and the disease’s natural history.¹⁰¹ The infection is categorized as a subclinical form, and the overt process is subdivided into acute-subacute or chronic disease. The acute-subacute pattern predominates in children and young adults, although the disease is also called the *juvenile form*, whereas the chronic disease affects adults and aged people and is thus called the *adult form*. According to the severity of the process, juvenile patients are assigned to two subgroups: severe and moderate. The adult form may be localized to pulmonary lesions, be unifocal disease, or be disseminated from its primary foci, the multifocal process. Disseminated

disease is characterized by involvement of the skin, mucosa, reticulo-endothelial system, adrenal glands, and, less frequently, the gastrointestinal or the genitourinary tract, bones, and central nervous system.^{11,106,154,162,210} The chronic form can be mild, moderate, or severe.¹⁰¹

Patients with acute or subacute disease develop signs and symptoms of a wasting process. Fever, malaise, listlessness, weight loss, and emaciation are recorded frequently. The severity of these symptoms is proportional to the degree of the organ involvement. Londero and associates reviewed the literature and found 269 cases in children younger than 14 years of age¹³⁰; however, sufficient clinical data for analysis of the prominent organ involvement were provided for only 77 children. The clinical characteristics exhibited by these children and by other patients reported subsequently, including the series of patients reported at two other centers, are shown in Table 202.2. These findings support the notion that juvenile paracoccidioidomycosis is a disease of the reticulo-endothelial system resulting in damage of the corresponding organs caused by severe macrophage dysfunction, as suggested previously.¹⁰² Superficial lymph node enlargement was the predominant sign (81.6%) in these cases. Cervical and submandibular lymph node chains were involved most commonly, followed by those of the supraclavicular and axillary regions; however, any chain can be affected (see Fig. 202.1). Lymph nodes may vary in size from slightly enlarged to large, painful, coalescent masses; they may be mobile and of elastic consistency or fixed to the adjacent tissues; hypertrophied nodes may progress to fistulization and discharge purulent material rich in *P. brasiliensis* yeast cells.

The next most important finding was hepatomegaly or splenomegaly (60.7%), which usually was asymptomatic. In a recent report of 102 cases of paracoccidioidomycosis in children younger than age 16, liver involvement was detected in 40%, of whom 68% presented with hepatomegaly and 29% with jaundice.²¹⁹ Liver enzymes, especially alkaline phosphatase and γ -glutamyltransferase, were frequently but not markedly increased.¹⁷⁷ Portal hypertension also was a rare occurrence. Importantly, those with liver involvement were younger and had more severe anemia, hypoalbuminemia, and malnutrition, and eventually higher risk for death.³⁹ Findings and complaints relating to the abdomen and digestive tract, such as presence of abdominal masses, lymph node enlargement, diarrhea, vomiting, abdominal distention or pain, and ascites, also have also been recorded in a sizable proportion of patients (see Table 202.2 and Fig. 202.2). Signs and symptoms of an acute abdomen, caused by masses formed by hypertrophied lymph nodes or perforation, also have been reported; this problem may lead to intestinal occlusion, blockage of lymphatic drainage, and, later, ascites.^{11,25,130,176,189}

In a series comprising predominantly patients with the juvenile form of the disease, abdominal radiographic studies (double-contrast barium) revealed ileal and jejunal alterations in 42% to 51%.^{97,146,147} The main findings were distortion and coarsening of the mucosal pattern and loop dilation. However, part of these alterations was probably nonspecific because jejunal biopsies performed in a small number of patients revealed neither granulomatous response nor *P. brasiliensis* yeast cells.¹⁴⁷ On the other hand, histopathologic examination of autopsies (likely the more severe cases) showed a specific granulomatous enteritis in 80%.⁹⁷ Additionally, in a magnetic resonance imaging study of patients, mostly with the juvenile form, 48% had abdominal lymph node enlargement, even if no abdominal signs and symptoms had been recorded.¹⁴⁵ This lymph node involvement can cause mesenteric lymphatic stasis and enteric mucosal edema that may progress to fungal enteritis accompanied by abnormal intestinal function such as reduced absorption of fat.^{147,176,189} Computed tomography and magnetic resonance imaging have proved helpful in determining the extent and nature of abdominal involvement.¹⁴⁷ Abdominal complications continue to be occasionally reported in more recent series.^{136,176,189}

Bone damage and articular problems also are important components (37.8%) of disseminated disease, especially in younger children. In these patients, the long bones were frequently affected, with the lytic lesions located at the diaphyseal or metaphyseal-epiphyseal regions,^{3,165} probably because of their higher vascularization, emphasizing the hematogenous dissemination that typically occurs in this form of the disease (see Fig. 202.3). Ribs, skull, phalanges, and vertebral lytic lesions also have been documented (see Fig. 202.3). Differently from the painful,

motion-restriction joint lesions, the bone lesions can be silent or oligosymptomatic.^{3,25,89,165} Pathologic fractures occasionally may occur.¹⁶³

Skin lesions were noted in 29.1% of the juvenile cases, with a tendency toward higher frequency with increasing patient age. Distribution of cutaneous lesions was variable, but face and trunk were involved more frequently.¹⁵⁴ Lung abnormalities were recorded in a smaller proportion of cases. However, even in the absence of clinical and radiologic involvement, colonization of the lung by *P. brasiliensis* can be demonstrated by direct examination and by culture.²¹¹ When chest radiographs were abnormal, enlarged hilar lymph nodes and miliary infiltrates predominated.^{106,130,211} In contrast to the adult form of the disease, in which adrenal involvement is a serious concern, it is uncommon in children. A survey of adrenal function before and after treatment in 23 children has shown normal adrenal function.¹⁹⁰

Anemia, an increased erythrocyte sedimentation rate, severe hypoalbuminemia, and hypergammaglobulinemia with high IgG serum concentrations are found regularly.^{11,25,102,177} Nonetheless, anti-*Paracoccidioides* antibodies may prove undetectable in some patients with localized disease and low fungal burden or because of the production of low avidity antibodies.¹⁷⁵ Eosinophilia, as well as elevated IgE antibody titers, has been detected in most patients.^{177,232,270}

The association between human immunodeficiency virus (HIV) infection and paracoccidioidomycosis has been investigated.^{20,166} However, the youngest patient reported was a 15-year-old boy who had enlargement of superficial and mediastinal lymph nodes, skin nodules, and pulmonary infiltrates.⁵⁸ The mycosis was also diagnosed occasionally in other patients whose immune function was depressed by certain conditions or medications.^{139,220} The incidence of this mycosis has not increased in HIV-infected patients as would have been expected.²⁰ No report of paracoccidioidomycosis and HIV coinfection in children has so far been published. In the chronic, progressive, adult form of paracoccidioidomycosis, signs and symptoms differ substantially from those found in children. Descriptions of the disease in adults are beyond the scope of this text but are referenced.^{154,226}

DIAGNOSIS

Specific diagnosis depends solely on laboratory confirmation.⁶⁸ The gold standard for paracoccidioidomycosis diagnosis is the direct observation of characteristic multiple-budding cells in biologic fluids and tissue sections or the isolation of the fungus from clinical specimens, but it may take up to 6 weeks to produce some results. In this sense, as an adjunct to clinical and histologic findings, the immunodiagnosis based on the detection of antibodies or fungal antigens is frequently used and is of a special value.⁶⁸

However, because of the discovery of different species, the serology of paracoccidioidomycosis is now a challenge for diagnosis because there is no universal antigen. This feature may have led to a substantial number of false-negative results.^{15,105} Since the mid-2000s, several molecular methods, such as PCR, have been developed for the detection of DNA from both species in clinical samples, providing high sensitivity and specificity rates.⁹⁴ The large cell, with multiple exospore, resembling a pilot's wheel, is pathognomonic of the disease (Fig. 202.4). The direct microscopic observation of the characteristic *Paracoccidioides* spp. should be done in a drop of physiologic saline or potassium hydroxide test.^{40,128} Usually, the sources of clinical specimens are sputum, secretion, and scraps or debris from ulcerated skin and mucosal lesions, draining material from suppurating lymph nodes or abscesses, bronchoalveolar fluid, biopsy tissue, and exfoliative cytology.^{51,78,244} Bronchoalveolar, articular, cerebrospinal, or other fluids must be centrifuged before examination. Draining material from suppurating lymph nodes usually is rich in fungal cells with multiple buds. Sputum is one of the most important specimens used for diagnosis, and various procedures are used to improve the detection of the organism in this specimen. When the first examination of the sputum is negative, it can be homogenized with an equal volume of *N*-acetyl-L-cysteine and then centrifuged again. Sodium or potassium hydroxide can be used, but only in direct examination because this treatment reduces the fungus isolation. The sensitivity of the direct examination (wet mount, smears, and histopathologic examination) varies from 80% to 100% or less and depends

FIG. 202.4 Direct examination of a potassium hydroxide mount of a patient's sputum specimen showing a budding *Paracoccidioides brasiliensis* yeast form-like cell.

on the laboratory.^{40,128,167} Biopsy samples should be taken only when routine direct examinations have failed, and the specimen should be placed in two separate flasks: one with sterile saline and the other with formalin buffered for mycologic and histopathologic examinations, respectively. Because the morphologic appearance of the parasitic forms of *P. brasiliensis* is pathognomonic, the diagnosis of the mycosis can be established by biopsy specimen and confirmed by either culture or serology. If the parasite is abundant, it may be identified by hematoxylin and eosin stain and confirmed by a special fungal stain such as periodic acid–Schiff or Gomori methods.^{128,225} Pereira and colleagues¹⁸⁹ established the diagnosis of 63 children with paracoccidioidomycosis by the identification of *P. brasiliensis* in lymph node biopsy (84%), bone biopsy (9%), or skin biopsy (7%) specimens.

When the disease is chronic, most of the fungal cells are found inside the macrophages, but free yeast cells predominate in disseminated cases. Pauciparasitic forms of the *Paracoccidioides* spp. granuloma that show a sarcoid pattern with rare yeast forms may appear. In these cases, the diagnosis may rely on epidemiologic data plus serologic and molecular diagnostic tools such as PCR on paraffin-embedded tissue.^{67,72,109,157,158} Visualization of the multiple budding yeast cells, in which the buds are connected to the parent cells by a narrow bridge with a well-defined refringent double wall, is mandatory because the *Paracoccidioides* spp. yeast cells may range from a few microns to 30 to 40 μm . Sometimes, in the lesions, the parasite is present as diminutive yeast cells, measuring about 3 to 5 μm .^{128,205} For this reason, the multiple budding structures always should be found for specific diagnosis. *Paracoccidioides* spp. blastoconidia may be confused with *Blastomyces dermatitidis*, capsule-deficient *Cryptococcus neoformans*, endospores and small *Coccidioides immitis* empty spherules, large *H. capsulatum* yeast cells,^{40,128} or even *Pneumocystis carinii*.²³⁵ In these cases, the molecular tests such as PCR and immunocytochemistry with specific polyclonal or monoclonal anti-*P. brasiliensis* antibody could be used.^{49,71,104,107,109}

Disseminated and pulmonary paracoccidioidomycosis both can be confused with tuberculosis, histoplasmosis, leukemia, malignant neoplasms, or Hodgkin disease. When the skin or mucous membranes are affected, paracoccidioidomycosis must be differentiated from histoplasmosis, leishmaniasis, leprosy, syphilis, lupus erythematosus, and a variety of malignant neoplasms. In children, tuberculosis, acute abdominal syndrome, intestinal obstruction, osteomyelitis, and rheumatic fever also are important considerations in the differential diagnosis of this disorder. Paracoccidioidomycosis should be considered as a differential diagnosis in cases of hypereosinophilia associated to massive splenomegaly in endemic areas to this mycosis.^{75,143}

Culture samples should be obtained to support the diagnosis and to establish the viability of the fungus. However, they are not always positive because the presence of other more rapidly growing microorganisms in the samples renders isolation difficult. At room temperature, *Paracoccidioides* spp. are a slow-growing fungus that can be overgrown readily by bacteria, yeasts (especially *Candida*), and contaminant molds.

Isolation should be attempted by the concomitant use of modified Sabouraud agar and yeast extract agar plus antibiotics and cycloheximide. In noncontaminated samples, the use of brain-heart infusion agar plus blood and antibiotics (without cycloheximide), a hemoglobin-containing agar incubated at 37°C, or both, also is advisable. Cultures should be observed for 4 to 6 weeks, depending on temperature of incubation, with a definitive classification being accomplished only in the yeast phase. The isolation rate of the fungus in culture varies from 80% to 100% but may be less in other nonspecialized centers.^{40,128} Because the mycelial form is not characteristic, subcultures in brain-heart infusion plus blood, Fava Netto's agar, or peptone–yeast extract–glucose agar, for up to 14 days at 35° to 37°C, allow yeast conversion to occur and definitive diagnosis to be established.^{125,128,206}

The correct identification of the species of *Paracoccidioides* that cause infection is important for the correct diagnosis and understanding of the clinical aspects of paracoccidioidomycosis. Several molecular markers—microsatellite, hsp70 indel, and prp8 intein—as well as multilocus, coding, and noncoding genealogies of mitochondrial and nuclear genes have been described to distinguish between species of *Paracoccidioides*.^{120,129,149,150,170,250,252} By using microsatellite marker system, *P. brasiliensis* S1 and PS2 can be differentiated,¹⁵⁰ but PS3 genotypes are not recognized, probably owing to the low diversity within this group.^{149,150,252} A PCR-based assay targeting an indel region in the HSP70 locus can reportedly selectively amplify *P. lutzii* isolates,²⁴⁷ and Theodoro and colleagues²⁵² successfully employed qPCR and SNaPshot reactions to detect single-nucleotide polymorphism among the cryptic groups in *P. brasiliensis* and *P. lutzii*. Recently, genotyping of *Paracoccidioides* has been applied using transposable elements (Trem A–H), and there is the possibility of differentiation between the two species, as well as using PCR restriction-fragment length polymorphism of the α -tubulin (*TUB1*) gene.²¹⁷

The species-specific gp43 gene of *P. brasiliensis* was detected by loop-mediated isothermal amplification in DNA from *P. brasiliensis* strains in 3 hours, suggesting that this method may be applied to rapid identification of this fungus.^{91,245} Recently, the identity of the *P. brasiliensis* typical and atypical strains could be confirmed by its dimorphism, by the expression of gp43, and by PCR using specific primers for gp43 as well as ribosomal internal transcribed spacer regions.^{35,197} However, an important note is that one sequence (483 base pairs) of the *L. loboi* gp43-like gene had 85% identity at the nucleotide level and 75% identity with the deduced amino acid sequences of the *P. brasiliensis* gp43 protein.²⁶⁶

Several *Paracoccidioides* spp. DNA sequences of potential diagnostic value have been reported,* but few have been applied to clinical samples, needing further study before they are introduced in diagnosis.^{28,43,104,109} *Paracoccidioides* spp. DNA sequences of potential diagnostic are a species-specific sequences of gp43 gene.^{28,104,109,245} A PCR assay based on sequence of the gene coding for the gp43 antigen presented the highest sensitivity and specificity.^{28,104,109} Although both species of *Paracoccidioides* express gp43 glycoprotein, there are some genetic differences in *P. lutzii* that hinder recognition by the primers used.¹⁰⁴ On the contrary, the Buitrago primers⁴³ apparently amplified both species.¹⁴⁹

Patients with paracoccidioidomycosis not only have a polyclonal B-cell activation but also produce large amounts of anti-*P. brasiliensis* antibodies, which are long-lasting and generally correlate with the severity of the disease.^{8,23,30,132,169,270} Assessment of the serologic response has long been used in paracoccidioidomycosis. It has been used as a diagnostic tool mainly because, in a significant proportion of the patients, it is difficult to obtain clinical specimens for visualization or cultivation of the fungus when only deep-sited lesions are present. On some occasions, a serologic result is the first indication of the mycotic nature of the patient's illness. In recent years, a great interest has been generated in the development of techniques to improve paracoccidioidomycosis diagnosis. These developments have come in the fields of either antibody or antigen detection. Thus serologic tests are of value for the diagnosis and may be useful in monitoring the evolution of the disease and its response to treatment. Antibodies are encountered in patients with clinical symptoms, and generally the titers of antibodies can be related

*References 28, 44, 71, 83, 104, 109, 127, 129, 213, 224, 245.

to the severity of the disease. Patients with paracoccidioidomycosis have a polyclonal activation of the humoral system with high serum concentrations of specific IgA, IgG, and IgE isotypes.^{8,27,30,132,157,270} However, antibodies usually are impaired or absent in some patients with severe juvenile forms and in immunocompromised individuals.^{80,264} On occasion, titer fluctuations may result in values below the level of detection by current methods, which may result in false-negative results. Experience over the years has resulted in various highly sensitive and widely employed serologic tests; the frequency of positive test results in patients with paracoccidioidomycosis varies from 70% to 95% and may even reach 100% in particular cases, depending on the type of test used and the stage of the disease. Of note is that discrepancies between serologic tests performed in different laboratories represent a problem because of the variation in reagents used, laboratory procedures adopted, and varying criteria used for evaluation of the results obtained.^{72,265} Some of the most critical reasons for discrepancies are variations in the type of antigenic preparations, different strains, and, indeed, the mycelial or yeast cell phase chosen. Culture filtrates, cytoplasmic extracts, and antigens derived from the cell wall have been used as reagents in serologic tests for paracoccidioidomycosis, although culture filtrates are used in most laboratories.^{15,48,72,81,122,158}

Various fractions that have been cloned, sequenced, and applied to the diagnosis include HSP60,⁶⁶ gp43,^{197,257} gp70,⁷⁶ and 27-kDa fractions^{62,182}, P2,⁴⁶ peptide derived from gp70 as well as the combinations of the previously described 27-kDa recombinant antigen and the 87-kDa heat shock protein,⁸⁷ as well as rPb27 and rPb40 antigens, which showed a sensitivity of 96% with a specificity of 100% in relation to control normal human sera and to sera from patients with other systemic mycoses and 93.5% to sera from patients with diverse infections.³⁵

Serologic methods that detect antigens or antibodies are extensively used and are useful for the diagnosis of paracoccidioidomycosis through the detection of gp43,^{197,257} the main antigen used for the immunodiagnosis of this disease caused by *P. brasiliensis*.^{49,157} However, the use of gp43 has become restricted because this marker is not identified in infections caused by *P. lutzii*.¹⁵ Gegembauer and colleagues¹⁰⁵ proposed that all sera from patients suspected of paracoccidioidomycosis should be tested against the traditional exoantigen of *P. brasiliensis* (AgPbB339) and the purified gp43 molecule. Reactive sera are considered paracoccidioidomycosis due to *P. brasiliensis*, and the nonreactive sera are then tested against cell-free antigen of *P. lutzii*.¹⁰⁵ It should also be pointed out that it is not desirable to use a single antigen preparation to diagnose paracoccidioidomycosis, a disease that is caused by highly diverse pathogens.^{131,149}

Many serologic tests have been developed and extensively studied. Agar gel immunodiffusion, complement fixation, and counterimmunoelectrophoresis tests have been employed extensively.¹⁵⁸ Also available are indirect immunofluorescence, indirect hemagglutination, enzyme-linked immunosorbent assay (ELISA), and dot-blot immunobinding and immunoblotting.^{158,242} Some of the newer tests have employed purified antigens, such as gp43, which are well characterized and more specific. Immunodiffusion and counterimmunoelectrophoresis, which employ crude antigens derived from the yeast phase, can detect 90% or more of active cases.⁷² Most authorities recommend the use of two different tests because none of these tests guarantees more than 90% sensitivity when it is employed alone. Immunodiffusion, for instance, is very simple and specific. Three precipitin bands, two of which are specific for *P. brasiliensis*, have been identified.^{27,40}

A joint effort of several diagnostic centers assessing the value of this test with use of a reference crude antigen (Ag7) demonstrated it to be 84.3% sensitive and 98.9% specific.⁷² Patients with very localized, benign disease may present negative results in these tests, but with more sensitive techniques (e.g., immunoblotting or gp43-ELISA), a diagnosis usually is reached. In our laboratory, three tests (immunodiffusion, counterimmunoelectrophoresis, immunoblotting) are used in a routine serologic diagnosis. The sensitivities of these tests were 85.3%, 92.9%, and 100%, respectively, evaluated against 120 paracoccidioidomycosis sera (data not published). Other studies have also described Western blot analysis as more a sensitive test.^{90,193} Limitations of these tests include cross-reactivity to other mycotic disorders, especially histoplasmosis and *L. loboi* antigens, mainly in more sensitive tests,¹⁹⁷ and difficulties in

standardization of the various tests and reagents.⁴⁸ The gp43 cross-reactivities were predominantly attributed to periodate-sensitive carbohydrate epitopes containing galactosyl.¹⁹⁷

The severe juvenile form of paracoccidioidomycosis affects children, adolescents, and young adults. Patients with the severe form generally present with counterimmunoelectrophoresis titers of $\geq 1/64$ or greater and lack of intradermal reaction to paracoccidioidin. Patients with mild forms present with counterimmunoelectrophoresis titers of less than one-sixteenth and a positive intradermic paracoccidioidin reaction.²³⁰

The value of serologic tests in the follow-up of patients undergoing treatment also has been addressed by several centers.¹⁵⁵ The value of these tests in monitoring patients also is problematic, partly because of the diversity and complexity of the humoral response in patients with paracoccidioidomycosis. Serial serologic evaluations, usually done 3 months apart, together with the clinical, mycologic, and radiologic surveys, can guide the treatment schedule, and two negative results in two of the serologic tests routinely employed is an additional criterion that helps in the difficult decision of therapy discontinuation.^{158,234}

The immunodiffusion, complement fixation, counterimmunoelectrophoresis, and ELISA tests were shown to be able to document the decline in antibody levels that parallels the clinical improvement; serum antibodies are cleared 1 to 2 years after cessation of therapy, depending on the clinical form.^{42,81,158} Conversely, in these circumstances, rising antibody levels indicate a relapse. Nonetheless, a considerable number of patients maintain, sometimes lifelong, the so-called healing titers (i.e., the persistence of low serologic titers in the tests). This is seen more frequently in patients with the acute form or the chronic multifocal form of the disease.⁸¹ The debate on the clinical relevance of this phenomenon—whether it represents the persistence of residual active lesions, thus predicting possible future relapses—is inconclusive. During treatment of paracoccidioidomycosis, an important consideration is to be able to establish cure or remission criteria. A significant fall in reactivity of anti-gp43 antibodies has been shown to correlate with clinical improvement. During relapses, the levels of specific antibodies rose, and some patients considered cured exhibited a residual reactivity. Some patients have a negative immunodiffusion and counterimmunoelectrophoresis test result but a residual reactivity with gp43 and gp70 by immunoblotting.^{40,81,87,157}

On the other hand, gp43 and gp70 can be detected in the biologic fluids. Furthermore, several studies have shown that the detection of antigens in blood and urine instead of antibodies is a potent means of establishing a diagnosis, monitoring treatment, and maintaining cure control.^{110,140,142,156,223,263} They allow a more precise diagnosis to be established for patients with disseminated childhood and adult multifocal disease, in which antibodies are undetectable because of their coupling to excess antigen or their incapacity to raise antibodies. Antigenemia follow-up studies permit a more precise determination of improvement because antigen load decreases with treatment response. The detection of circulating antigen may represent a more practical approach to the early and rapid diagnosis of the disease.⁶⁷ It also will be very helpful in establishing the diagnosis of immunocompromised patients, especially those with acquired immunodeficiency syndrome (AIDS), in which searching for an antibody response is not a completely reliable diagnostic tool.

The skin test with paracoccidioidin is not considered a diagnostic test because 30% to 50% of the patients are nonreactive when they are tested initially.^{55,99,144} Conversely, a positive skin test result indicates previous contact with the fungus but not necessarily active disease. When histoplasmin skin test material is used, cross-reactions may be verified.⁹⁹ When the result of the skin test with paracoccidioidin is negative and the patient is treated, the skin test result may become positive, in which case the patient's prognosis is considered good.^{40,128,174,206,230}

TREATMENT

Different classes of effective antifungal compounds are currently available that reduce the mortality of paracoccidioidomycosis. In addition to the prolonged use of antifungal drugs, an adequate humoral and cellular immune response is required to fully control the mycosis.²²⁹ Cellular

immunity, however, may be impaired in a large number of patients because of malnutrition or the disease process itself^{1,25,169}; providing supportive therapy, therefore, is important. Rest, adequate nutrition, correction of anemia, and treatment of other concomitant infections are also recommended.¹⁵⁵ In children, the precise total duration of therapy is variable according to the severity of the disease and as such should also be dictated by the clinical and serologic responses of the patient to treatment. The importance of continuous treatment must be emphasized because relapses occur if the drug is not taken regularly.

Paracoccidioidomycosis is the only fungal disease that can be treated successfully with sulfa drugs. Sulfadiazine was largely employed in the past for patients with mild or moderately severe disease, or for patients who had been treated initially with amphotericin B,¹⁵⁵ but currently it is rarely used because of its inconvenient posology and side effects. However, in some centers sulfadiazine is still available and is provided orally at daily doses of 60 to 100 mg/kg divided in four to six equal parts to children; in adults, a maximum daily dose of 6 g can be used. Water intake and urine alkalization (usually by bicarbonated water intake) should be encouraged during therapy to prevent crystalluria and tubular deposits of sulfadiazine.^{155,231} Duration of the treatment is dictated by the patient's response after clinical and serologic improvements have been attained; in general, in the chronic form, at least 6 months are required. Treatment with sulfadiazine was in general followed by administration of slow-acting sulfa drug (sulfamethoxypyridazine or sulfadimethoxine) as maintenance treatment, at a maximum daily dosage of 1 g. Resistance to sulfonamides has already been documented.²⁰⁷ Sulfadiazine has been replaced, especially in Brazil, which accounts for 80% of all cases in South America, by trimethoprim-sulfamethoxazole (80 mg of trimethoprim and 400 mg of sulfamethoxazole per tablet). This combination drug is also used in association with amphotericin B. Tolerability is good; myelotoxicity (leukopenia) is the main side effect and can be monitored and controlled by folic acid administration without modification of the therapeutic regimen. The Brazilian consensus on paracoccidioidomycosis recommends 8 to 10 mg/kg of trimethoprim daily²³⁴; however, in adults it is given generally at a dose of two tablets administered orally at 12-hour intervals with satisfactory results. This combination has the advantage of permitting alternative parenteral administration whenever necessary; in this case it can be administered from 12- to up to 6-hour intervals. Duration of the acute treatment with this drug varies in each case, but it usually lasts for 6 months. Maintenance treatment in these cases can be achieved by using one half the dose of the acute treatment or by using a slow-acting sulfa. Development of resistance to trimethoprim-sulfamethoxazole is occasionally clinically suspected but has rarely been documented in vitro. There is a single report of resistance of an isolate from an adult patient with the subacute form.¹¹⁴

Amphotericin B is effective but should be reserved for severely disseminated cases.^{25,155} It also can be used by patients who relapse during the course of or after treatment with orally administered drug because gastrointestinal involvement may impair drug absorption in these cases. The effectiveness of therapy with azoles has curtailed the need for more aggressive regimens. More than one course of therapy may be required in some patients.

There is a report of the successful amphotericin B-sulfonamide combination treatment in adults.¹³⁷ Data regarding effectiveness of the new amphotericin B lipid formulations in paracoccidioidomycosis are still limited. A series of 28 patients with severe disease treated with amphotericin B lipid complex showed good results in all cases; however, only one child was included in this study.^{85,187}

Ketoconazole is now rarely considered in the therapy of paracoccidioidomycosis because of its side effects and numerous drug interactions compared with other triazole derivatives for oral administration (itraconazole, fluconazole).^{203,229} Today, more experience has been gained with itraconazole.^{38,56,155,172} This triazole is more potent and less toxic than ketoconazole and is equally or even more effective than the parent compound. It is administered in 100-mg capsules that should be given with or shortly after a meal. One to two capsules, depending on the severity of the fungal process, taken daily for 6 months have been shown to be effective in reducing all active lesions. Most (98%) of the patients,

including children and young adults, respond.^{155,172} Posttherapy observations in predominantly adult series indicate variable proportions (ranging from 2.1% to 21%) of relapses depending on the severity of the disease, duration of therapy, and time of follow-up.^{135,255} Side effects have been few and include transient elevation of hepatic enzymes.^{155,172,255} The Brazilian consensus on paracoccidioidomycosis suggests itraconazole as a second option after trimethoprim-sulfamethoxazole, based on the more limited experience in children with this compound compared with the latter (or with amphotericin B),²³⁴ but recent reports are encouraging, and itraconazole, at least for adult paracoccidioidomycosis, has become the first treatment choice in many reference centers. A randomized trial with sulfadiazine, ketoconazole, and itraconazole for the treatment of adult patients with disease of moderate severity failed to show higher efficacy of a particular regimen over the others.²³¹ However, two recently published studies with a larger number of patients and more extended follow-up suggested the superiority of itraconazole over trimethoprim-sulfamethoxazole; the most consistent difference between the two treatments was the shorter time to achieve cure with itraconazole.^{38,56} Unfortunately again, both studies addressed mostly adult patients, and predominantly those with the chronic form of the disease. Itraconazole in children is recommended at a dose of 5 to 10 mg/kg daily, with a maximum dosage of 200 mg twice daily. A liquid formulation of itraconazole in cyclodextrin was initially suggested as a promising alternative for children treatment, but it has not been marketed in countries where the disease is endemic, and thus far no clinical experience could be gathered to support its recommendation.

Fluconazole is not as effective in this disorder; higher doses, up to 600 mg/day, and longer treatment periods should be considered. Recrudescence and relapse of disease apparently occur more frequently than when itraconazole is used.^{25,155} Fluconazole may be useful in severely ill patients who must be treated intravenously.¹⁵⁵ No experience in children is available. The literature has only one report of the successful use of terbinafine in an adult patient.¹⁸⁰ Voriconazole is an extended-spectrum triazole antifungal agent that is available in both oral and intravenous formulations. In vitro susceptibility data show that *P. brasiliensis* is highly sensitive to voriconazole. A pilot open-label study showed that it is well tolerated and as effective as itraconazole for the treatment of chronic paracoccidioidomycosis.²⁰¹ However, this drug is not approved for pediatric use.

Isavuconazole, a new triazole agent, can be administered orally or intravenously and has been tested in few patients with paracoccidioidomycosis with promising results, in agreement with its good in vitro anti-*Paracoccidioides* activity. Further studies with larger number of patients with the juvenile form of the disease are required to determine its place in the treatment of children with the mycosis.²⁵³

Many questions remain to be answered regarding optimal treatment of paracoccidioidomycosis. The role of adjunct therapy with immunomodulators, such as peptides derived from the immunodominant glycoprotein form *P. brasiliensis* that act by augmenting the Th1-mediated immune responses, has been investigated mainly in experimental models of the disease and showed promising results.²²¹ Two studies demonstrated some reactivity of patients' T cells to these peptides.¹²¹ Further studies are required to demonstrate their utility in promoting protective cell-mediated immune responses in the human host. α -Glucan obtained from *Saccharomyces cerevisiae* with immunoenhancing properties has been preliminary investigated, but further studies are needed.¹⁵³ In the opposite direction, some investigators have administered short courses of corticosteroids as adjunct therapy to severe cases, based on the rationale that the failure to improve with antifungal therapy observed in these cases was due to uncontrolled or excessive inflammatory response.^{18,113} Some fatalities were attributed to the exacerbated inflammatory response.^{19,26} The clinical and laboratory criteria that allow reduction in the antifungal dose or that could be used to end treatment with the assurance that the patient is cured are not established. Progressive decrease in the titers of the serologic tests currently available is one of the laboratory parameters used most frequently. Newer methods (e.g., antigenemia detection and molecular biology approaches) still need further standardization and clinical studies and have not yet become widely available.^{110,140,142} Meanwhile, most specialists agree that treatment decisions need to be tailored according to the patient.

PROGNOSIS

Paracoccidioidomycosis has no prophylaxis. Vaccine strategies are being developed but are still restricted to experimental models of the disease.^{243,258} The mycosis can be fatal if left untreated, but currently this has seldom been observed.^{19,26,115,192,219} On the other hand, sequelae remain a problem. Residual lesions have been observed in a few patients with no known history of active mycotic infection.^{101,106,154}

Prognosis depends on the status of the patient at the time of diagnosis. Children and young adults in whom fungemia has taken place and who have multiple organ involvement may respond less well to therapy. The fatality rate in young patients at one time was reported to be 31%,⁵⁵ but it now is much lower as a result of earlier diagnoses and better treatments. Nevertheless, it remains a life-threatening disease with 6% fatalities in the most recent series.³⁹ This was attributed to delayed diagnosis or searching for medical assistance, irregular treatment, or treatment not monitored. Abdominal complications, especially liver involvement, ascites, and malnutrition, were associated with the lethal prognosis.^{11,39,176,189} In the adult group, mortality rates are much lower. After specific treatment is instituted, lesions regress promptly; skin lesions may heal completely in 2 to 4 weeks.¹⁵⁵ Complete remission is expected for most patients with the acute-subacute and chronic form of the disease. Prognosis has improved as a result of earlier diagnosis, new antifungal drugs that facilitate compliance, and better knowledge of the disease. The latter has provided better clinical and laboratory follow-up and the notion that the disease needs prolonged surveillance, as shown by the decrease in positive mycologic tests during and after therapy.^{155,255} Some investigators consider the term *cure* inappropriate because of the inability to confirm complete eradication of the organism; the term *apparent cure* should instead be used.¹⁵⁵

Paracoccidioidomycosis persists as a disease with relatively low mortality but high morbidity. Complications vary and, like prognosis, their occurrence depends on the extent of fungal invasion. In the juvenile form, early complications that may lead to surgical intervention are intestinal obstruction and jaundice, both of which result from enlarged mesenteric lymph nodes. Disabsorptive syndromes may be associated, aggravating the nutritional status of the patients.^{21,233} Patients also may present with ascites or chylothorax. Lymph nodes may suppurate, and fistulas can develop. A late complication that has been described is abdominal malakoplakia.²¹⁸ In the adult form, acute complications of mucosal involvement are dysphagia and dysphonia,²⁶⁸ edema of the glottis, respiratory insufficiency, and Addison disease,¹⁵⁴ among others.²⁵⁹ Sequelae are not as common in children as in adults. In general, fibrosis is the cause of serious problems in patients who respond to therapy, particularly when extensive pulmonary infiltrates are present. Despite the newer, very effective therapies, these sequelae preclude, in a proportion of the cases, the complete restoration of the patients' previous health status.^{164,154,155,172,255} In the former group, scarring and fibrosis of the affected nodes and residual pulmonary fibrosis have been noted.¹³⁰ Malabsorption syndrome probably is the most serious sequela in the juvenile form because of the enteric loss of proteins and inflammatory cells that results in immunodeficiency and opportunistic infections.^{21,233}

Acknowledgments

We thank Professor Angela Restrepo for her invaluable contribution to this version of the chapter and Drs. Ana Marisa Fusco Almeida, Maria Gorete Nogueira, and Ricardo Pereira for their comments and sharing unpublished material. We also thank Irani Coito for the bibliography revision.

Cryptococcosis

203

David L. Goldman • John R. Perfect

Cryptococcus neoformans is an encapsulated yeast that causes meningoencephalitis and pneumonia in both immunocompetent and immunocompromised children. Since its identification as a pathogen in 1894,¹²² great strides have been made in our understanding of the biology and the pathogenesis of cryptococcosis. The incidence of cryptococcosis greatly increased in association with both the acquired immunodeficiency syndrome (AIDS) epidemic and improvements in health care, which have resulted in an increased number of individuals at risk for cryptococcosis. We have also come to recognize *C. neoformans* comprises at least two separate species, *C. neoformans* and *Cryptococcus gattii*, that evolved from each other more than 40 million years ago.⁴⁶ Disease caused by these two species is similar in many ways, but there are important differences. Despite the availability of antifungal therapy, the mortality associated with cryptococcosis remains high, and new therapies and prevention strategies are needed.

ORGANISM

C. neoformans is an encapsulated basidiomycete that is evolutionarily distinct from yeasts like *Candida albicans* and more closely related to corn and grain plant fungal pathogens.⁷⁷ *C. neoformans* is a round yeast (5 to 10 μm diameter) that produces white (frequently mucoid) colonies on standard mycologic media. *C. neoformans* can also form giant cells (also known as titan cells) that can be as large as 80 to 100 μm diameter, which have been described primarily in the context of animal models of infection.⁵⁶ The capsule varies greatly in size among strains and its size is regulated by the local milieu. *C. neoformans* is capable of sexual reproduction in the laboratory, and mating types (alpha and A) have been identified. In the environment and during infection, the organism is typically haploid and replicates asexually.

C. neoformans was originally classified into five serotypes (A, B, C, D, and AD) based on its reaction with anticapsular serum. Serotypes B and C, formally known as *C. neoformans* var. *gattii*, are now collectively named *C. gattii*. This species is now further classified into four genotypes (VGI, VGII, VGIII, and VGIV), with VGII genotype being further classified into types, VGIIa, VGIIb, and VGIIc. Serotype A (also known as *C. neoformans* var. *grubii*) is responsible for the vast majority of *C. neoformans* disease and is now classified into three main genotypes (VNI, VNII, and VNB). Serotype D (*C. neoformans* var. *neoformans*) is primarily

found in Europe, and occasionally hybrids such as serotype A/D and other diploid strains are found in nature.

C. neoformans and *C. gattii* can be distinguished by a variety of biochemical, serologic, and molecular typing techniques, although these are not routinely available in clinical microbiology laboratories. For instance, *C. gattii* (but not *C. neoformans*) produces blue coloration on L-canavanine, glycine, and bromothymol blue (CGB) medium. Recently, matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) has been demonstrated to be useful in making the distinction between these two cryptococcal species.⁵¹ Other species of *Cryptococcus* (e.g., *Cryptococcus laurentii*, *Cryptococcus albidus*) are less virulent and rarely have been reported to cause disease.^{12,57}

Virulence

Several important virulence traits common to *C. neoformans* and *C. gattii* include encapsulation, melanization, the ability to grow at 37°C, and both urease and phospholipase production. These characteristics are not uniformly present in other cryptococcal species. The emergence of some of these traits has been hypothesized to have been selected for because of survival advantages they confer in their natural environment, where these yeasts are exposed to invertebrate predatory scavengers such as nematodes and amoebae.

Capsule

The impressive capsules of *C. neoformans* and *C. gattii* are composed of long unbranched polymers of xylose and glucuronic acid. The capsule plays a central role in cryptococcal virulence, and acapsular and hypocapsular mutants exhibit greatly reduced virulence.²³ Although capsules can be produced by other cryptococcal species, studies suggest that there are important differences in the biophysical properties between the capsule of virulent and nonvirulent species.⁸ Capsule size is actively regulated in response to local conditions such as PCO₂, serum, and iron. In nature, the small capsule likely protects the yeast from desiccation and ingestion by soil amoebae. However, entering the mammalian host environment signals the enlargement of the capsule around the yeast and gives the organism its distinctive appearance in India ink staining (Fig. 203.1). The substantial polysaccharide material forming the capsule is extensively shed into host tissue, cerebrospinal fluid (CSF), and blood during infection; and the detection of this shed polysaccharide forms

FIG. 203.1 (A) India ink staining of cerebrospinal fluid demonstrates *Cryptococcus neoformans* and capsule, which excludes the stain and results in a halo around the organism. (B) Computed tomography scan of a child with rhabdomyosarcoma reveals nodule (white arrow) secondary to *C. neoformans*. (C) Mucicarmine staining of a lung from a rat with experimentally induced pulmonary cryptococcosis shows granulomas containing *C. neoformans* (black arrows). (D) Immunostaining for cryptococcal polysaccharide reveals extensive shedding of polysaccharide within the brain parenchyma and around cryptococcomas of a rat with experimentally induced cryptococcal meningoencephalitis.

the basis of the cryptococcal antigen (CRAG) testing. Similar to prototypical pediatric pathogens (e.g., *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Neisseria meningitidis*), the cryptococcal capsule inhibits antibody- and complement-mediated phagocytosis and thereby interferes with the development of an effective immune response.⁹⁴ However, the capsule also exhibits a variety of other antiinflammatory properties, including inhibition of leukocyte migration,⁴⁴ enhanced interleukin-10 secretion,¹⁷³ inhibition of T-cell proliferation,¹⁸³ and induction of macrophage apoptosis.¹⁷⁸ In addition, the cryptococcal capsule also has been hypothesized to contribute to deadly cerebral edema⁷¹ and to promote replication of the human immunodeficiency virus (HIV).¹⁴¹ Given the central role of the capsule in cryptococcal pathogenesis, administration of capsular-specific antibody has been studied as potential adjunctive therapy in animal models to remove antigen and improve host elimination of the yeasts.^{124,151} However, this therapeutic approach has so far found limited success in humans.⁹⁹

Melanin

Melanin is a pigment that is synthesized from catechol precursors (e.g., dopamine, epinephrine) by the laccase enzymes of *C. neoformans* and *C. gattii*. The laccase enzyme is similar to enzymes produced by wood-rotting fungi and is capable of digesting lignin, an important constituent of trees, and may thereby promote growth of the yeast in decaying trees. Melanin is produced during cryptococcal infection and is localized to the cell wall.¹⁴⁷ Melanin content can vary significantly among individual *C. neoformans* strains.¹⁸¹ However, yeast mutants lacking the ability to produce melanin are less virulent in animal models than their melanin-producing parental strains. Although melanin structure remains poorly understood, its chemistry endows it with the ability to stabilize free radicals and provides a stable framework even under extremely harsh

environmental conditions. These characteristics likely play an important role in the capacity of melanin to protect against damage caused by nitrogen- and oxygen-derived host oxidants in addition to exogenous factors such as ultraviolet light and antifungal agents. Melanin also appears to promote disease through its immunomodulatory properties⁷⁶ and its ability to bind to host antimicrobial peptides.¹²⁷ One explanation for cryptococcal neurotropism relates to the hypothesis that high concentrations of catechol precursors within the brain promote cryptococcal melanization, which in turn protects the organism from the host immune response within the brain.¹⁴⁴

Extracellular Enzymes

C. neoformans and *C. gattii* also produce a variety of extracellular enzymes that have been linked to virulence, including proteinase, phospholipase, and urease. Urease catalyzes the hydrolysis of urea to ammonia and carbamate. The importance of urease in virulence and during infection appears to depend on the infection site and may be more important for pulmonary infection than brain infection.³⁷ Urease production by *C. neoformans* has been associated with the accumulation of immature dendritic cells and the production of a disease-enhancing helper T-cell subtype 2 (Th2) inflammation.¹³⁰ It may also promote entry into the brain, across the blood-brain barrier.¹⁵⁶ *C. neoformans* strains vary in their phospholipase production, and high phospholipase production has been associated with increase fungal burden in animal models.¹⁷⁶ Conversely, lack of phospholipase production has been linked to reduced virulence of a cryptococcal strain.³⁶ Phospholipases have also been implicated in promoting entry into the brain³⁵ by facilitating passage through brain endothelial cells.¹¹⁵ Phospholipases may also promote intracellular growth by releasing arachidonic acid from host cells.¹⁸² Other virulence factors that have been identified include mating type,⁹⁷

prostaglandin production,⁵⁰ calcineurin signaling,^{161,129} and several stress response pathways involving protein kinase A and trehalose.¹⁴²

Phenotypic Variation

Recent studies highlight several processes by which strains of *Cryptococcus* undergo significant phenotypic variation during infection, which in turn promotes disease pathogenesis. This includes the formation of giant or titan cells that can be 20 times the size of a typical cell (reviewed in reference 184). These Titan cells typically exhibit increased ploidy and are more resistant to phagocytosis.³⁸ Other processes by which *Cryptococcus* undergoes significant phenotypic changes include phenotypic switching,⁵⁸ replicative aging,¹⁶ and quorum sensing.⁴ These phenotypic changes are bolstered by vibrant genome plasticity during stresses in the host.^{73,81} Furthermore, we can now begin to see how this yeast responds to the human environment by capturing its transcriptome at the site of infection.³⁰

ECOLOGY AND EPIDEMIOLOGY

Cryptococcus neoformans

There are important differences in the ecology of *C. neoformans* and *C. gattii* (Table 203.1). *C. neoformans* (but not *C. gattii*) is well known for its association with bird droppings, including those from pigeons, canaries, and parrots. *C. neoformans* is capable of growth in the acidic environment of bird droppings. Nonetheless, birds are unlikely to be the primary environmental source for *C. neoformans* because their high internal temperatures inhibit *C. neoformans* growth and possibly possess innate avian host factors against this yeast. In addition, the *C. neoformans* density is much higher in aged pigeon droppings compared with fresh droppings, suggesting the possibility for secondary contamination as the mechanism for this ecologic niche.¹⁰⁹ Other primary environmental sources for *C. neoformans* include rotting trees and fruits.^{31,111}

There are also important differences in the epidemiology of disease caused by these different species of *Cryptococcus*. *C. neoformans* is generally considered an opportunistic pathogen that causes central nervous system (CNS) and respiratory disease in patients with depressed cellular immunity. However, cryptococcosis secondary to *C. neoformans* also occurs in individuals without any identified risk factors. A dramatic increase in the prevalence of cryptococcosis occurred in association with the AIDS epidemic. In patients with HIV infection, cryptococcal meningoencephalitis (CME) is an AIDS-defining diagnosis, typically occurring in both adults and children with profound immunodeficiency, as evidenced by a finding of CD4⁺ T cells less than 100/μL. In countries where highly active antiretroviral therapy (HAART) has been successfully introduced, the prevalence of cryptococcosis has greatly decreased. Unfortunately, cryptococcosis has emerged as a significant cause of disease in AIDS patients in countries with limited resources. Worldwide, most cases of cryptococcosis occur in sub-Saharan Africa and Southeast Asia, affecting an estimated 1 million individuals annually¹³⁵ and up to

30% of AIDS patients.¹⁴ Although this number has shrunk with the widespread introduction of antiretroviral therapy worldwide, the prevalence remains high. In South Africa, *C. neoformans* is the leading cause of meningitis in adults, with an incidence more than twice that of tuberculous meningitis.⁸³ In developed countries, an increase in the incidence of *C. neoformans* disease among non-HIV-infected individuals has been recognized. This appears to be primarily associated with improvements in medical care and an increase in the number of individuals receiving immunosuppressive therapy, especially organ transplant recipients and other immunosuppressants such as steroids and anti-tumor necrosis factor therapies. Among solid-organ transplant recipients, cryptococcosis is the third most common invasive fungal infection. Among non-HIV-infected patients with cryptococcosis in the United States, 20% to 60% are transplant recipients.¹⁷⁷ Interestingly, *C. neoformans* var. *grubii* has been increasingly reported as a cause of disease in individuals from China (including children) without any recognized immune deficit.⁷⁵

Overall, cryptococcosis secondary to *C. neoformans* is less common in children than adults but remains an important cause of pneumonia and meningoencephalitis, especially in certain parts of the world. Owing to the rarity of pediatric cryptococcosis, the precise prevalence is difficult to define and may vary by region. Studies of US children with AIDS in the 1990s estimated an incidence of cryptococcosis to be about 1%.⁶⁰ A more recent US series identified 63 cases of pediatric cryptococcosis from a consortium of 42 children's hospitals over a 5-year period, with an admission rate of 6.2 per million hospitalizations.⁸⁶ Most children (63.5%) in this cohort had underlying immunosuppression, whereas 21% were immunocompetent and 16% had AIDS. The 8-year point prevalence of cryptococcosis among Thai children with AIDS was 2.97%.¹⁰⁷ A study from South Africa reported 361 cases of pediatric cryptococcosis over a 3-year period, representing 2% of all cases of cryptococcosis over this time.¹¹⁸ The reported median age at time of diagnosis of pediatric cryptococcosis varies from 7 to 12 years. In most series, pediatric cryptococcosis rarely occurs in children younger than age 1 year, although in the South African cohort an increased incidence was noted within the first year of life. In addition to AIDS, cryptococcosis has been identified in children with a variety of primary and secondary immunodeficiency states, including organ transplantation, lymphoma, leukemia, lupus, glucocorticoid therapy, sarcoma, hyperimmunoglobulin M syndrome, Bruton agammaglobulinemia, and severe combined immunodeficiency.^{5,80,102,162,180} Neonatal cryptococcosis is rare but has been described (see later discussion).

Although the incidence of symptomatic cryptococcosis is disproportionately low in children, serologic studies suggest that children from certain regions of the country may be infected with *C. neoformans* at a very young age.⁵⁹ The basis for this discrepancy between serologic findings and clinical disease is unknown. It is likely that most pediatric infections are asymptomatic or misdiagnosed as viral disease. Potential reasons for the low incidence of symptomatic pediatric cryptococcosis

TABLE 203.1 Summary of Characteristics of *Cryptococcus gattii* and *Cryptococcus neoformans*

	<i>Cryptococcus gattii</i>	<i>Cryptococcus neoformans</i>
Microbiology	Serotypes B and C Molecular type VGI associated with Australia and VGIIa with outbreak in Pacific Northwest Bluish discoloration on CGB media Distinction can also be made by MALDI-MS	Serotypes A and D Molecular type VNI most common cause of <i>C. neoformans</i> diseases
Ecology	Eucalyptus and other trees	Bird droppings and trees
Epidemiology	Immunocompetent > immunocompromised Endemic in certain tropical/subtropical regions Outbreak in Pacific Northwest	Immunocompromised (especially AIDS and T-cell defects) > immunocompetent High incidence in sub-Saharan Africa and Southeast Asia Decreased incidence in regions where HAART is available
Clinical manifestations	Primary pulmonary infection and CNS cryptococcomas with associated complications	Meningoencephalitis and disseminated disease a common presentation, especially among AIDS patients

AIDS, Acquired immunodeficiency syndrome; CGB, L-canavanine, glycine, and bromothymol blue; CNS, central nervous system; HAART, highly active antiretroviral therapy; MALDI-MS, matrix-assisted laser desorption/ionization time of flight.

include the time needed to reactivate infection, the importance of repeated exposures, and differences in infecting strains.¹²⁰ Nonetheless, it remains a perplexing issue as to why many children appear to be infected but rarely develop disease.

Cryptococcus gattii

In contrast to *C. neoformans*, *C. gattii* was initially recognized as a disease of tropical regions and endemic in Australasia, where it is associated with eucalyptus trees (both river red and forest red gum trees). However, *C. gattii* has been increasingly recognized to cause disease outside Australasia and tropical regions. Over the past 15 years, *C. gattii* has been linked to an outbreak of disease in the Pacific Northwest. This outbreak was initially recognized on Vancouver Island with subsequent extension into the United States (including the states of Washington and Oregon). Cryptococcosis secondary to *C. gattii* may occasionally occur in travelers returning from the Pacific Northwest. Disease typically presents within weeks to months after travel but may occur as long as 1 year after travel.⁶⁶ In the Pacific Northwest, *C. gattii* has been isolated from non-eucalyptus tree species (Douglas fir, alder, and Garry oak), soil, air, fresh water, and sea water. There are also *C. gattii* cases being reported outside the geographic boundaries typically associated with *C. gattii* disease,¹¹⁶ including areas east of the Mississippi in the United States.⁹⁶ This change in the environmental location of *C. gattii* may be the result of genetic changes in the yeast or climatic changes that allow the organism to successfully compete in new geographic regions.

Cryptococcus gattii causes disease in both immunocompetent and immunocompromised individuals, although disease appears to be more common among immunocompetent individuals compared with *C. neoformans*. In the Pacific Northwest outbreak, corticosteroid use and older age (>50 years) have been associated with increased severity.⁶⁷ In an Australian study of *C. gattii* disease, 72% of patients were found to have no recognizable immune deficit.²⁹ Some investigators, however, have hypothesized that apparently “normal” individuals infected with *C. gattii* may have subclinical immune deficits,¹¹⁴ including autoantibodies to granulocyte-macrophage colony-stimulating factor.¹⁴⁸ Because standard microbiologic techniques fail to distinguish between the two species, the precise prevalence of *C. gattii* disease is not yet known.

The incidence of cryptococcosis secondary to *C. gattii* in children is not well characterized. Of 218 cases of cryptococcosis secondary to *C. gattii* in British Columbia between 1999 and 2007, four cases (1.8%) occurred in children younger than 18 years.⁵³ In contrast, among 43 cases of *C. gattii* meningoencephalitis in a series from Brazil, 19% occurred in children younger than 12 years.¹⁵²

PATHOGENESIS

C. neoformans and *C. gattii* infections are believed to be acquired through inhalation of infectious propagules within the environment. The precise infecting form remains to be understood and may involve either desiccated yeast cells or small basidiospores (1 to 2 μ m), thus allowing alveolar deposition. Once within the lung, infection may cause disease through progression of pneumonia and dissemination to the CNS. Alternatively, infection may be contained in a dormant site within the lungs and reactivate in the setting of subsequent immunosuppression, such as HIV infection or corticosteroid use. Evidence for reactivation disease includes molecular typing⁵⁵ and pathologic⁶⁹ and serologic studies.¹⁵⁰ Furthermore, recent reports of very early cryptococcosis after organ transplantation highlight the tendency of *C. neoformans* to cause latent infections within transplanted organs.¹⁶⁴ Differences in the propensity for *C. neoformans* and *C. gattii* to cause primary progressive disease may exist. For example, molecular typing studies and cases of cryptococcosis among returning travelers to the Pacific Northwest highlight the potential for *C. gattii* to cause primary progressive disease.^{19,22} These findings are consistent with findings from animal experimentation.⁹⁵ Within the lung, both innate and adaptive immune responses are essential to the effective control of yeasts that can survive in both the intracellular and extracellular environment of the host. *C. neoformans* can be recognized by the cells of the innate immune system through a variety of

receptors, including toll-like, β -glucan, and mannose receptors. Both classically and alternatively activated macrophages play a central role in the host immune response.¹⁵⁴ Dendritic cells, natural killer cells, neutrophils, and activated macrophages can kill the yeast. *C. neoformans* is a facultative intracellular pathogen and is well adapted to survive and replicate within the acidic environment of the phagolysosome.¹⁰⁴ Unlike other intracellular pathogens, *C. neoformans* does not employ typical strategies to escape or modify the phagolysosomal compartment. However, intracellular yeast survival within the harsh environment of the phagolysosome is supported by virulence traits, including capsule production, melanization, secretion of extracellular enzymes, and prostaglandin production. Interestingly, *C. neoformans* can escape the macrophage through induction of cell lysis or phagosomal extrusion.⁶ The latter process allows the transfer of yeasts between macrophages without inducing macrophage death and its associated inflammation. This novel mechanism likely promotes the intracellular persistence of *C. neoformans*.

Adaptive immunity and T-cell-mediated activation of macrophages are central to the successful host immune response. The critical importance of T-cell immunity in the protective host response to cryptococcosis is highlighted by the increased susceptibility of individuals with defective T-cell immunity to cryptococcosis, such as with HIV-infected individuals. Animal experimentation conclusively highlights the protective nature of Th1 immunity and the nonprotective (disease-enhancing) nature of Th2 immunity.^{72,90} In this regard, *C. neoformans* and *C. gattii* virulence have been linked to their ability to actively modulate the inflammatory response and to elicit nonprotective Th2 inflammation.^{2,39} It should also be noted that increasing evidence suggests that B cells and humoral immunity also play a part in the effective immune composite response against cryptococcal infection.¹⁴⁶

PULMONARY CRYPTOCOCCOSIS

The lungs are the most commonly recognized body site of cryptococcal disease after the CNS. Pulmonary cryptococcosis can present as the primary manifestation of cryptococcosis (e.g., without extrapulmonary disease) or in association with disseminated disease or meningoencephalitis. Symptomatic pulmonary cryptococcosis typically occurs in individuals with underlying immunodeficiency or chronic lung disease. Nonetheless, pulmonary cryptococcosis in individuals without recognized risk factors is well described and appears to be more common for infection secondary to *C. gattii*. In one study of HIV-negative patients with cryptococcosis, 15% of patients with pulmonary cryptococcosis had no underlying disease.¹³⁴ Among AIDS patients with cryptococcal meningoencephalitis, pulmonary cryptococcosis has been reported to be present in a wide range (10–55%) of patients.¹⁸ This variation may occur as a result of the nonspecific features of pulmonary disease along with differences in diagnostic evaluation within cohorts.

Case reports and series describing adults with primary pulmonary cryptococcosis first appeared in the 1960s. Initial descriptions of this disorder highlighted the chronic, nonspecific nature of pulmonary cryptococcosis and a tendency for it to occur in older white men.²⁰ Although primary pulmonary cryptococcosis occurs in apparently normal hosts, several underlying conditions (in addition to HIV) have been identified as risk factors. These include corticosteroid use, chronic lung disease, Cushing syndrome, diabetes mellitus, malignancy, tuberculosis, rheumatologic disease, and chronic obstructive pulmonary disease.^{3,134} Among patients with cancer, a lymphoid malignancy is present in most patients with pulmonary cryptococcosis, as is corticosteroid use and lymphopenia.⁹³ In the mid-2000s reports highlighted the risk for anti-tumor necrosis factor therapies and pulmonary cryptococcosis, similar to that for tuberculosis and other endemic mycosis.⁶⁵ In a multicenter study of organ transplant recipients, 39% of patients with cryptococcosis had primary pulmonary disease.¹³² Primary pulmonary cryptococcosis has also been reported to be disproportionately more common in the British Columbia *C. gattii* outbreak, where it is the most common form of presentation.⁵⁴ Nonetheless, the specific presentation of *C. gattii* disease may still be primarily dependent on host immune status.²⁹

Pulmonary Cryptococcosis in Children

Pulmonary disease as the primary manifestation of cryptococcosis in children is uncommon but has been described and affects both immunocompetent and immunocompromised children.^{60,131} Infected children usually have chronic respiratory tract symptoms (i.e., cough, fever, chest pain, and weight loss) and are initially treated for bacterial pneumonia before the diagnosis is suspected. In one review of pulmonary cryptococcosis in children, a predilection for lower lobe lung disease was apparent, with most children being asymptomatic, immunocompromised, and male.¹⁶⁷ Children may be asymptomatic and the diagnosis recognized as a result of imaging performed for other reasons. Several characteristic cases of pediatric pulmonary cryptococcosis in the context of soft tissue malignancy were diagnosed as a result of imaging to evaluate for metastasis.^{5,167} These children all had lung nodules that were initially thought to represent metastatic disease, and they were often lymphopenic.

Clinical Manifestations

The typical symptoms of pulmonary cryptococcosis in all age groups include cough, chest pain, dyspnea, fever, and weight loss.^{20,91} However, several studies indicate that a significant proportion of infected patients do not have respiratory symptoms. In a study of pulmonary cryptococcosis among solid-organ transplant recipients, 38% of the cases were asymptomatic.¹⁵⁷ Asymptomatic disease appears to be more common among immunocompetent individuals but, as previously noted, does occur in immunosuppressed patients and may be initially confused with cancer. In patients with recognizable pulmonary disease, symptoms are typically mild and often chronic. In immunocompetent individuals, primary pulmonary cryptococcosis is often self-limited. In contrast, pulmonary cryptococcosis among immunocompromised individuals is more likely to occur in the context of disseminated disease or progress to involve the CNS. Constitutional signs, especially fever, weight loss, and anorexia, have been described, particularly in association with the underlying immunosuppression. Rarely, pulmonary cryptococcosis can rapidly progress to acute respiratory distress syndrome in the severely immunocompromised patient. Coinfection with other pathogens, including *Mycobacterium tuberculosis* and *Aspergillus* spp., occasionally has been described.^{49,172}

Radiology

The three most common radiologic appearances of pulmonary cryptococcosis are nodular (see Fig. 203.1), infiltrative, and interstitial, although pleural effusions and cavitary disease have also been described.^{32,92} Nodules may be solitary or multiple and are nonspecific. Among AIDS patients, interstitial disease and large lobar infiltrates are the most common radiologic findings. Diffuse interstitial findings may be an indication of disseminated disease. Nodular densities or mass lesions are more likely to be asymptomatic or incidentally detected pulmonary cryptococcosis than pleural effusions and infiltrates.¹⁵⁷ Cavitation of cryptococcal nodules, progressive infiltrates, or acute respiratory distress syndrome may occur, especially immunocompromised individuals, and these features have been described in the context of immune reconstitution inflammatory syndrome (IRIS, see later discussion) in AIDS patients⁸⁴ and transplant recipients.

Diagnosis

Sputum culture has an extremely limited sensitivity in the diagnosis of pulmonary cryptococcosis. In one study, only 19 of 101 cases of pulmonary cryptococcosis in adults were confirmed by sputum culture.²⁰ Bronchoscopy with lavage fluid testing for fungal culture and cryptococcal polysaccharide antigen may aid in the diagnosis of cryptococcosis, although the sensitivity of this approach can be variable. Definitive diagnosis may require obtaining tissue directly through either trans-thoracic, transbronchial, or open-lung biopsy. Serum cryptococcal antigen is typically nondetectable in isolated pulmonary cryptococcosis, and the presence of serum antigenemia supports at least consideration of disseminated disease.

CRYPTOCOCCAL MENINGOENCEPHALITIS

CME typically involves the subarachnoid space or leptomeninges and is usually associated with brain parenchymal involvement even if

cryptococcomas are not observed radiographically. Infection may extend through the Virchow-Robin space into the brain substance, most commonly affecting the midbrain and basal ganglia. Immunohistochemistry studies of brains from patients reveal extensive shedding of cryptococcal polysaccharide into the brain parenchyma (see Fig. 203.1).¹⁰⁰ Subarachnoid and parenchymal inflammation ranging from minimal to extensive granulomas may be present, depending on the host immune status and the fungal burden.¹⁰¹ Increased intracranial pressure (ICP) often complicates CME and contributes significantly to the morbidity and mortality of this disease (see later). Cryptococcomas and CNS complications, including hydrocephalus and cranial nerve palsies, appear to be more common with *C. gattii* disease^{123,160} but can occur with *C. neoformans*. Differences between CME in HIV-infected and non-HIV-infected individuals have also been described. These include a more acute presentation and the presence of a second site of infection in HIV-infected individuals,¹⁰⁵ with less associated inflammation.

The mechanisms by which *C. neoformans* and *C. gattii* enter the CNS are still incompletely understood. In general, organisms cross the blood-brain barrier by one of three mechanisms: transcellularly, paracellularly, or through infected phagocytes (Trojan horse). Evidence for both transcellular²⁴ and Trojan horse mechanisms exist for *Cryptococcus*. In this regard, *C. neoformans* adheres to and infects endothelial cells in vitro.⁷⁹ This process may be active and involve the secretion of enzymes (e.g., urease, phospholipase metalloprotease), which in turn induces cytoskeleton rearrangements, or signaling that results in movement across the blood-brain barrier.^{115,179,85} Evidence supporting the Trojan horse model comes from experiments in which CNS infection was successfully produced by infection of mice with *C. neoformans*-infected monocytes.²⁷

Clinical Manifestations

CME is a subacute to chronic process that generally presents symptomatically over weeks to even months. Occasionally, shorter and longer time intervals are described. Affected patients typically have a persistent headache with or without a variety of other nonspecific symptoms, including fever, lethargy, nausea, and vomiting. Meningismus and photophobia, which are typical of bacterial meningitis, are often absent in adults. Symptoms of encephalitis may also be present and even predominate, including personality changes, memory loss, and altered mental status. Patients with cryptococcomas can have signs of increased ICP and localizing neurologic symptoms and signs, consistent with an intracranial mass.

Pediatric Cryptococcal Meningoencephalitis

Because of the small number of cases, it is difficult to know if there are specific clinical differences in pediatric compared with adult meningoencephalitis in the presentation. The most common symptoms reported in the largest pediatric series to date are headaches and fever. Other commonly reported symptoms include nausea and vomiting. In one study of affected African children with AIDS, seizures were significantly more common in children compared with adults (38% vs. 11%); however, this high incidence of seizures has not been reported in other pediatric series.⁶⁴ Additional reported symptoms include altered mental status, focal neurologic deficits, photophobia, abdominal pain, and respiratory symptoms. In some studies, meningismus is present in the majority of children. In a recent study of Colombian children with cryptococcosis, the most common symptoms were headache (78.1%), fever (68.8%), nausea and vomiting (65.6%), confusion (50%), and meningeal signs (37.5%).¹¹⁰ Like adults, it is common to see a relative lack of CSF inflammation in children with cryptococcal meningoencephalitis, and CSF profiles may be at almost normal. Increased ICP in pediatric CME is well described, but the precise incidence is not well documented. In one study, more than 80% of children with CME had increased ICP with or without symptoms.¹⁰⁷

Diagnosis

Cerebrospinal Fluid Profile

The CSF profile of both adults and children with CME is characterized by a lack in both cellularity and alterations in biochemical profile, especially in HIV-infected individuals. In pediatric studies, mean CSF

white blood cell counts vary from 4 to 16 cells/mm³.^{1,74,153} In another study, approximately 50% of infected children had normal CSF findings (with a normal white blood cell count of <7 cells/mm³).¹⁰⁷ Likewise, CSF protein and glucose concentrations are often normal, although elevated protein concentrations may be present, especially with obstruction. In one study, decreased glucose or increased protein concentrations were present in 19% of infected children.¹⁰⁷ Given the normal appearance of CSF, a high suspicion and cryptococcal specific studies (see later discussion) are necessary for diagnosis.

Imaging

In cryptococcal meningoencephalitis, imaging often underrepresents the extent of disease, although magnetic resonance imaging results are more likely to be abnormal.²⁶ The presence of imaging abnormalities may be a marker of more extensive disease and high risk for death.⁴⁵ Meningeal enhancement is not uniformly present, which likely reflects the paucity of inflammation in this disease. In a study of solid-organ transplant recipients with cryptococcal meningoencephalitis, meningeal enhancement (the most common finding) was present in only 15% of patients.¹⁵⁸ A similar frequency of enhancement has been reported in patients with AIDS. Other imaging features that may occasionally be noted include parenchymal masses (see later discussion), dilation of the Virchow-Robin spaces, hydrocephalous, and cerebral edema.^{41,145} Lesions of the Virchow-Robin spaces (called “soap bubble” lesions) are nonenhancing on magnetic resonance imaging and occur at the level of the thalamus, basal ganglia, periventricular white matter, and cerebellum. These lesions correlate with invasion through the perivascular Virchow-Robin spaces seen on autopsy and are characteristic of meningoencephalitis.⁹

India Ink Staining

India ink staining is based on the exclusion of the dye by the *C. neoformans* or *C. gattii* capsule, which creates a halo around the cell against a dark background. The sensitivity of India ink staining of CSF has been reported to vary from 50% to more than 80%. The sensitivity of this assay depends on the number of organisms in the CSF, which may in part be dependent on the immune state of the host.³⁴ False-positive results may be reported from leukocytes and tissue cells that can be removed by treatment with potassium hydroxide.

Culture and Histopathology

In adults with CME and HIV infection, CSF and blood cultures are positive in 75% to 90% and 70% of patients, respectively. Similar numbers have been reported in pediatric series.¹ For patients who undergo biopsy (e.g., brain biopsy for cryptococcoma), *C. neoformans* or *C. gattii* is best visualized with special stains, including silver stain and stains that label the capsule (e.g., mucicarmine and Alcian blue). As with other fungi, the cell wall of this organism can be visualized with fluorescence using calcofluor, whereas melanin can be detected with a Fontana-Masson stain. Detection of the organism by immunohistochemistry using capsule-specific antibody and polymerase chain reaction has also been described (see Fig. 203.1).^{167,174} Although not part of routine clinical practice, quantitative CSF yeast counts and their serial measurements have been used on a research basis to predict prognosis and treatment success.¹⁵

Antigen Detection

The polysaccharide capsule is shed during infection and can be measured in serum, CSF, and bronchoalveolar lavage fluid using two different antibody-based technologies (latex agglutination and enzyme-linked immunosorbent assay). Currently, latex agglutination is the most commonly used assay in clinical laboratories. This is a semiquantitative assay, which is reported as a titer. The sensitivity and specificity of antigen detection (using CSF or serum) for patients with CME are both more than 95%. Antigen may also be detected in the serum in more than 90% of patients with disseminated disease.¹¹ As noted earlier, high CSF antigen titers have been associated with increased mortality, presumably reflecting a high fungal burden. In fact, CSF fungal burden can reach more than 1 million yeasts per milliliter of CSF in advanced cases. In patients with extremely high antigen titers, a false-negative

agglutination test may result from a prozone phenomenon. This can be addressed by dilution of samples. Care should therefore be taken in interpreting negative result in patients in whom there is a high clinical suspicion. Rare false-positive results have been reported in patients with infections secondary to other fungal pathogens such as *Trichosporon* spp.^{117,169} and other microbes.²⁵ Although antigen detection assays are useful in diagnosis, they have limited utility in following response to therapy. A lateral flow assay (LFA), which shows good agreement with standard antigen testing, has been developed for the diagnosis of cryptococcosis, especially in resource-limited countries.¹⁰⁸ This assay offers the advantages of rapidity, ease of use, and decreased cost. Like other antigen detection techniques, the LFA has limited utility in following the effectiveness of therapy. Interestingly, limited data suggest that initial LFA testing results may correlate with fungal burden and prognosis.⁸⁷ In resource-limited areas or areas with known high prevalence of cryptococcosis, the point-of-care, simple, cheap LFA may be integrated into a preemptive strategy for HIV-infected patients to identify and treat early disease.¹⁷⁵

Complications

Mortality

Untreated CME is uniformly fatal. Despite the development of a variety of antifungal therapies, the mortality associated with cryptococcosis, particularly CNS and disseminated disease, remains high. Worldwide there are more than an estimated one-half million deaths annually, with the majority of these deaths occurring in sub-Saharan Africa and Southeast Asia.¹³⁵ Overall, cryptococcal meningitis is the fourth leading infectious cause of death in sub-Saharan Africa, surpassing even tuberculosis.¹³⁵ In solid-organ transplant recipients, the mortality associated with CME can approach 40%.⁷⁸ This is comparable to the 10% to 30% mortality for HIV-associated cryptococcal disease in developed countries. In pediatric series, mortality rates have been reported to range between 23% and 38%.^{1,64,153} Mortality is affected by several variables, including the underlying immune status, the presence of brain involvement, and the availability of appropriate antifungal therapies. Predictors of mortality reflect host factors and yeast burden and thus include a high CSF cryptococcal antigen titer, increased ICP, altered mental status, positive India ink staining, and low CSF white blood cell counts at baseline (<10 cells/mm³).^{7,43,149}

Increased Intracranial Pressure

Increased ICP is an important and common complication of cryptococcal meningoencephalitis, occurring in as many as 60% of adult AIDS patients with this fungal infection. Increased ICP appears to be more common in patients with *C. gattii* disease, who also tend to have more cryptococcomas. The precise incidence of increased ICP in children with CME is not known but is likely to be similar to that in adults.¹⁰⁷ The entity is well described in children and includes cases of fulminant ICP.¹²⁵ The basis of increased ICP in CME remains unknown, but possible mechanisms include (1) inflammation, (2) osmotic effects of shed polysaccharide or mannitol, and (3) obstruction of normal CSF drainage pathways (e.g., arachnoid villi) by cryptococcal polysaccharide or obstructing yeasts. In support of this latter hypothesis, increased ICP has been associated in some studies with higher CSF fungal burden and CSF cryptococcal antigen levels but not with inflammation.⁶² Furthermore, a difference in the tendencies of individual strains to elicit increased ICP has been demonstrated in animal models.⁵³

Increased ICP is a recognized risk factor for early mortality in cryptococcal meningoencephalitis^{62,171} and may correlate with increased CSF fungal burden, increased CSF cryptococcal antigen levels, and failure to sterilize CSF at 14 days. Patients with increased ICP may have symptoms (e.g., hearing loss, altered mental status, cranial nerve palsy), but increased ICP may not be clinically apparent. Furthermore, computed tomography usually does not reveal ventricular dilation, although occasional cases of obstructive hydrocephalous on presentation have been described. Appropriate treatment of CME therefore includes the documentation of CSF opening pressures at the initiation of therapy. Symptomatic increased opening pressure (≥ 250 mm³ of H₂O) should be managed by serial lumbar punctures with daily withdrawal of CSF or a lumbar drain. Although there have been no controlled studies to

determine the best approach to lowering ICP, the most recent Infectious Diseases Society of America (IDSA) guidelines suggest removal of enough CSF to decrease pressure by 50% if it is extremely high or to a normal pressure of less than 200 mm³ H₂O.¹³⁹ Temporary percutaneous lumbar drains or ventriculostomy for persons who require repeated daily lumbar punctures should be considered. Permanent ventriculoperitoneal shunts may be indicated in patients who fail less-invasive methods. Acetazolamide and mannitol are not indicated in the treatment of increased ICP and may be detrimental.

Corticosteroids are also generally not indicated in the treatment of increased ICP associated with CME, although this paradigm is based primarily on data from HIV-infected cohorts.⁶³ A recent prospective double-blinded study for the use of dexamethasone during induction therapy for CME was conducted in Asia and Africa to better define the effects of adjunctive steroids on CME-associated mortality in HIV-infected individuals. In this study the tapering doses of dexamethasone had no benefit on mortality but did appear to have increased adverse events and reduced killing of cryptococci in the subarachnoid space.¹³ Corticosteroid therapy should not be routinely used during induction therapy for CME. A potential role for corticosteroids in the treatment of severe, recalcitrant elevated ICP in association with *C. gattii* disease has been hypothesized, but more studies are needed before this practice is routinely accepted.⁵² Importantly, successful treatment of increased ICP in association with IRIS with corticosteroids has been described in case reports and small series, and its use remains an important management strategy when IRIS is diagnosed during CME.¹⁰³

Cryptococcoma

Intraparenchymal brain lesions (cryptococcomas) are a recognized complication of CME and have been associated with increased mortality.^{26,158} Lesions may be singular or multiple, occur in 11% to 35% of patients,¹⁴⁵ and can be associated with focal neurologic symptoms and hydrocephalus. Cryptococcomas appear to be more common in non-AIDS patients and those with *C. gattii* disease. In a recent study of *C. gattii* meningoencephalitis in Australia, 37% of patients developed radiographic cryptococcomas.²⁹ The treatment of cryptococcomas has not been studied in a prospective manner, and current recommendations are based on small series and expert opinion. These recommendations highlight the importance of extended duration for therapy induction and prolonged maintenance antifungal therapies. In patients with large lesions (≥3 cm), consideration should be given to surgical debulking.¹³⁹ Repeat imaging is helpful in monitoring the response of brain lesions to therapy, but lesions may persist radiographically for a long time and can develop surrounding edema in the context of effective antifungal therapy. This dynamic change can interfere with the assessment of size and evaluation of response to therapy. Intraparenchymal brain lesions also occur in the context of IRIS (see next discussion).

IMMUNE RECONSTITUTION INFLAMMATORY SYNDROME

IRIS is thought to occur as a result of improved immune function in the context of residual microbial antigens, which, in turn, produces symptoms secondary to enhanced inflammation. The current paradigm is that IRIS represents a dysregulated immune response with exaggerated Th1 response relative to Th2 inflammation. Support for this hypothesis comes from studies elucidating the CSF cytokine pattern in individuals with IRIS.¹⁶⁸ IRIS in association with cryptococcosis was initially described in AIDS patients treated with HAART, although it has subsequently been described in solid-organ transplant recipients,¹⁶⁵ pregnant patients,⁴⁸ and apparently normal hosts.⁴⁷ Cryptococcal IRIS may unmask a previously unrecognized infection (unmasking IRIS) or occur after treatment of cryptococcosis, resulting in a paradoxical worsening of symptoms (paradoxical IRIS). IRIS has not been particularly well documented in children. In a recent study of South Africa children, IRIS was felt to contribute to increased ICP and lymphadenopathy, leading to substantial morbidity and mortality in affected children.⁶⁸

The lack of precise clinical criteria for a diagnosis of cryptococcal IRIS has hindered the study and management of this phenomenon. Several essential elements for this diagnosis have been proposed,

including: (1) appearance or worsening of clinical or radiologic manifestations consistent with an inflammatory process; (2) symptoms occurring during receipt of appropriate antifungal therapy that cannot be explained by a newly acquired infection; and (3) negative results of cultures or stable or reduced biomarkers for the initial fungal pathogen during the diagnostic workup for the inflammatory process.¹⁵⁹ Physicians considering a diagnosis of IRIS should exclude progression of infection (owing to inadequate antifungal therapy, antifungal resistance, or worsening immune function) and alternative diagnoses (e.g., other infection, malignancy). Cryptococcal IRIS may present in the form of lymphadenitis, pneumonia, meningitis, or space-occupying lesions in the CNS. Histopathology of affected lymph nodes typically reveals granulomatous inflammation with necrosis and few or absent fungal forms. Cultures typically reveal no growth. Patients with CNS IRIS may develop headache, fever, neck stiffness, and increased ICP, and the associated morbidity and mortality may be significant.⁸⁸ In patients with AIDS, cryptococcal IRIS has been reported to occur days to years after initiation of HAART, but typically it occurs weeks to months after HAART is begun. There is usually an associated decline in HIV viral load (at least 1 log₁₀), although changes in CD4⁺ T cell counts are more variable. Risk factors for cryptococcal IRIS among HIV patients include lower baseline CD4⁺ T cells, higher HIV viral load, and higher fungal burden at the initiation of therapy. With transplant recipients, IRIS may occur with rapid lowering of an immunosuppression regimen.

There is controversy on the role of early institution of HAART and the development of IRIS. Delayed initiation of HAART may be associated with progression of HIV disease as with other opportunistic infections. However, increasing evidence identifies early initiation of HAART in the context of cryptococcal meningitis as an important risk factor for IRIS.^{112,113,155,166} In a recent randomized controlled trial of HIV-positive adults from South Africa and Uganda with CME, patients who received earlier HAART (1–2 weeks after CME diagnosis) had a 15% higher mortality rate at 26 weeks compared with patients for whom HAART was deferred for 5 weeks after diagnosis (45% vs. 30%).¹⁷ Based on these observations, HAART is generally started after CME diagnosis and treatment initiation from 4 to 10 weeks.

Specific treatment of cryptococcal IRIS has not been well studied. Minor IRIS manifestations may resolve spontaneously without specific therapy. Recent IDSA guidelines suggest that prednisone 0.5 to 1 mg/kg in conjunction with antifungal therapy may be helpful for the treatment of CNS cryptococcal IRIS or the use of tapering doses of dexamethasone.¹³

OTHER FORMS OF CRYPTOCOCCOSIS

Besides the CNS and pulmonary tract, *C. neoformans* disease may affect a wide range of organ systems. Primary cutaneous disease may occasionally occur as a result of direct inoculation.¹²⁶ More commonly, cutaneous disease represents secondary dissemination, especially in immunocompromised hosts.^{138,163} The clinical presentation varies and may include acneiform lesions, purpura, vesicles, nodules, abscesses, ulcers, granulomas, pustules, draining sinuses, and cellulitis. In patients with AIDS, cutaneous cryptococcosis may appear similar to molluscum contagiosum. A high clinical suspicion, along with tissue sampling, is therefore needed to make a diagnosis. The presence of skin disease should prompt an evaluation for disseminated disease. The prostate has been hypothesized to serve as a sanctuary for *C. neoformans* during antifungal therapy and thereby promote recurrent infection. *C. neoformans* has been isolated from prostatic secretions of AIDS patients with disseminated infection, during and after treatment.⁹⁸ The clinical significance of these observations, however, remains unclear, and routine surveillance of prostatic secretions is not indicated.

Congenital Cryptococcosis

Congenital cryptococcosis is rare. More than a dozen cases of cryptococcosis in early infancy (e.g., within the first 3 months of life) have been reported, with a mortality greater than 50%.¹³⁷ Disease is typically multisystemic, usually with involvement of the central nervous and respiratory systems. Early (e.g., within hours to days of life)²¹ and late presentations⁸⁹ of cryptococcosis (weeks to months) have been described

in neonates. Based on the timing of disease, it has been hypothesized that infection can be transmitted both transplacentally and perinatally, possibly through the aspiration of infected material. The rarity of congenital cryptococcosis among women with active cryptococcosis during pregnancy indicates that the placenta is extremely effective in limiting maternal-fetal transmission. This notion is further supported by several descriptions of cryptococcal placentitis without neonatal disease.⁴⁰

TREATMENT

The treatment of cryptococcosis depends on both the type of disease and the underlying immune status of the host. Although there are clinical differences in cryptococcosis secondary to *C. neoformans* and *C. gattii*, there are no differences in treatment recommendations at the present time. There are no clinical trials addressing the treatment of cryptococcosis in children. Therefore, current pediatric recommendations are based on extrapolations from adult studies using known pharmacokinetic profile of antifungal drugs in children. Routine testing for antifungal susceptibility is not indicated because resistance to amphotericin B and fluconazole is rare. Furthermore, minimal inhibitory concentration (MIC) cutoffs for fluconazole susceptibility have not been established and do not always correlate with clinical outcome. In one study of 487 isolates, only 3 (0.6%) demonstrated a high fluconazole MIC (i.e., ≥ 16 $\mu\text{g/mL}$), and all isolates were inhibited by very low concentrations of amphotericin B and exhibited very low MICs to voriconazole and posaconazole.⁶¹ The IDSA guidelines suggest testing for antifungal susceptibilities only in the context of relapsing disease.¹³⁹

Pulmonary Disease

In patients with pulmonary disease, it is essential to determine whether there is associated extrapulmonary involvement. To this end, testing serum for cryptococcal antigen and CSF analysis should be considered in all patients with CNS symptoms and in those with underlying immunosuppression even without symptoms. Isolated pulmonary disease in an immunocompetent patient, which is not severe and asymptomatic, can be treated with fluconazole and without lumbar puncture. The dosage of fluconazole for pulmonary disease in children is 6 to 12 mg/kg per day for 6 to 12 months based on resolution of symptoms (not to exceed the adult dosage of 400 mg daily). Itraconazole is an alternative therapy for individuals who cannot tolerate fluconazole, and the successful use of extended-spectrum azoles (e.g., voriconazole, posaconazole, and isavuconazole) has been described.^{140,143,170} Patients with evidence of extrapulmonary disease or severe pulmonary involvement should be treated with the same approach used to treat meningoencephalitis. Azoles are contraindicated in early pregnancy.

Central Nervous System Disease

The currently recommended treatment strategy for CME involves a staged approach using amphotericin B with flucytosine in combination for induction followed by consolidation treatment with fluconazole. The IDSA Guidelines for the Management of Cryptococcal Disease recommend amphotericin B at 0.7 to 1 mg/kg per day plus flucytosine 100 mg/kg per day for the treatment of cryptococcal meningitis.¹³⁹ In children, who tolerate amphotericin B better than adults, the higher dosage (e.g., 1 mg/kg per day) is preferred. In adults, there has been a significant shift toward lipid formulations of amphotericin B such as AmBisome 3 to 6 mg/kg per day because of amphotericin B deoxycholate nephrotoxicity. It is unclear in children whether the lipid formulation will carry this therapeutic advantage. The combination of amphotericin B and flucytosine has been demonstrated to be synergistic in vitro and result in improved outcomes in both animal models and clinical studies.⁴² Both amphotericin B and flucytosine have significant toxicities, and patients must be closely monitored for these treatment complications. The duration of induction therapy is typically at least 2 weeks but should be individualized. A longer duration of induction should be considered under the following conditions: lack of clinical improvement, positive CSF cultures at 2 weeks, the inability to administer flucytosine, HIV negative, and non-transplant recipient. Most meningoencephalitis

studies have been done in patients with AIDS and in transplant recipients, and the duration of induction therapy for other individuals with CME has not been well studied. Repeated CSF examination at 14 days should be considered to document CSF sterilization. Patients with persistently positive CSF cultures should continue induction therapy, and CSF analysis should be repeated every 2 weeks until CSF is sterile. If flucytosine cannot be administered, amphotericin B administered alone is an acceptable alternative or with high-dose fluconazole.¹²¹ In patients whose renal function is impaired, lipid formulations of amphotericin B (liposomal amphotericin B 3 to 6 mg/kg per day, or amphotericin B lipid complex 5 mg/kg) may be substituted. Lipid formulations of amphotericin B are also recommended as first-line agents for solid-organ transplant recipients with cryptococcosis. In resource-limited regions where amphotericin B is not readily available, high-dose fluconazole (1200 mg/day) with flucytosine has been studied as an alternative in adults.¹²⁸ After successful induction therapy, children should be treated with fluconazole 12 mg/kg per day (adult dosage, 400 mg) for 8 weeks.

Secondary Prophylaxis

After successful therapy for pneumonia and meningoencephalitis, children with AIDS should be maintained on suppressive fluconazole therapy (6 mg/kg per day, not to exceed the adult dosage of 200 mg daily) to prevent recurrence of disease. In adults, the current recommendations are to continue fluconazole until patients demonstrate a response to HAART, as manifested by a CD4 cell count greater than 100/ μL and a sustained undetectable or very low HIV RNA level for 3 months (with a minimum of 12 months of antifungal therapy).¹³⁹ Although this approach is generally applied to children, there are few clinical data to support this practice, and it should be undertaken with caution and with close observation for recurrence. A 6- to 12-month period of suppressive fluconazole therapy should also be considered in organ transplant recipients.¹³⁹

Adjuvant Interferon- γ

Consistent with its action as a Th1 cytokine, interferon- γ (IFN- γ) plays a central role in the effective host response to cryptococcosis in animal models.^{10,28} Furthermore, exogenously administered IFN- γ enhances resistance and potentiates the effects of amphotericin B in these models.^{33,70} A phase II study demonstrated that adjuvant IFN- γ is well tolerated in patients with cryptococcal meningoencephalitis.¹³³ In another study it was suggested that the addition of IFN- γ to initial induction with amphotericin B or flucytosine results in quicker CSF sterilization, a marker that has previously been associated with clinical success.⁸² This study, however, was not powered to detect differences in mortality. Current IDSA guidelines recommend that adjuvant IFN- γ should be considered in refractory cases.¹³⁹

Primary Prophylaxis

In resource-limited regions where HAART is not widely available, there has been increased interest in fluconazole prophylaxis to prevent cryptococcosis. The rationale for this approach lies in the high incidence and mortality of cryptococcosis in these regions. Two different strategies have been applied with promising results. With the first preemptive approach, at-risk HIV-infected individuals are regularly screened for serum cryptococcal antigenemia and treated with fluconazole if they are antigenemic but without overt cryptococcosis.¹¹⁹ Cryptococcal antigenemia is a marker for the subsequent development of symptomatic cryptococcosis and for death from cryptococcosis and other causes.¹⁰⁶ In essence, this approach represents treatment of incipient disease and is similar to the preemptive strategy used in cytomegalovirus disease in solid-organ transplant recipients. This approach may become more attractive with the recent development of the LFA for antigen detection. With the second approach, all at-risk individuals (i.e., those with CD4 T cells $<200/\mu\text{L}$) are prophylactically treated with fluconazole. In a Ugandan prospective, double-blind randomized controlled trial, fluconazole prophylaxis for all patients with CD4 T cells less than 200 μL was effective in preventing cryptococcosis and cryptococcosis-associated death,¹³⁶ but this strategy can be costly, increase adverse drug events, and potentially encourage drug-resistance development.

Histoplasmosis

204

Martin B. Kleiman • Elaine G. Cox • John C. Christenson

Histoplasmosis is the most common pulmonary and systemic mycosis in humans, and it affects millions of people.^{211,428} Although most infections occur in areas where the etiologic agent, *Histoplasma capsulatum*, is highly endemic, histoplasmosis is being recognized in areas not previously known to be endemic. Substantial proportions of infections with *H. capsulatum* occur in the United States, where approximately 500,000 persons are infected annually.⁴²¹ Of these, an estimated 55,000 to 200,000 infected persons become symptomatic.⁷⁰ During 2001 to 2012, histoplasmosis-associated hospitalizations in the United States were estimated to be 50,778.³¹ Histoplasmosis was the primary diagnosis in approximately 20% of cases, with infection rates lowest in persons younger than 18 years old. The significance of *H. capsulatum* as a cause of opportunistic infection has escalated in proportion to the increasing numbers of persons who are immunosuppressed.²⁶⁶ Although an increase in hospitalizations has been observed in transplant recipients and in those receiving biologic agents, the proportion of hospitalizations in patients with human immunodeficiency virus (HIV) infection or acquired immunodeficiency syndrome (AIDS) decreased from 2001 to 2012 (from 21.5% to 17.3%).³¹

H. capsulatum was described first in 1906 by Darling^{88,89} during examination of autopsy specimens of a man who died of a chronic, wasting illness. He observed organisms within histiocytes and thought them to be encapsulated plasmodia. In 1932, Dodd and Tompkins described intracellular *H. capsulatum* in the peripheral blood smear of a febrile child, and DeMonbreum isolated the organism and correctly classified it as a fungus.

In 1944, Christie and Peterson⁶⁹ developed histoplasmin and, after cutaneous inoculation, showed a localized reaction in a child with histoplasmosis. In 1945, Parsons and Zarafonitis characterized the disease as rare and usually fatal after studying 71 patients with disseminated histoplasmosis. Broader use of histoplasmin skin testing by Christie and Peterson,⁶⁹ however, showed histoplasmosis to be a common and usually mild disease. They also determined that histoplasmosis was the cause of pulmonary calcifications in patients who were presumed to have had tuberculosis but whose tuberculin skin test results were negative. Demonstration of the organism in soil and air samples in the late 1940s and early 1950s confirmed the natural habitat and transmission of the pathogen.^{5,120,478}

FIG. 204.1 Culture of *Histoplasma capsulatum* from sputum illustrating tuberculate macroconidia and microconidia (lactophenol cotton blue, $\times 52$).

ORGANISM

Histoplasma capsulatum var. *capsulatum* is a thermally dimorphic, saprophytic fungus. At temperatures of 25°C to 30°C, the mold grows as a fluffy colony with an aerial mycelium that varies from white to buff brown. Mycelia, small oval microconidia (2–4 μm) that are attached laterally to hyphae, and tuberculate and nontuberculate macroconidia (8–6 μm) are seen microscopically (Fig. 204.1). Growth is slow, with 1 to 2 weeks required for laboratory strains and 8 to 12 weeks for growth from clinical specimens. When cultured at 37°C on enriched media containing cysteine, the mold transforms to the yeast form in 7 to 10 days. The small, heaped, yellow-white, pasty colonies appear microscopically as ovoid, budding yeasts (1–3 $\mu\text{m} \times 3$ –5 μm) with rare pseudohyphae.²⁹⁴

In its natural habitat, the soil, *H. capsulatum* exists as spore-bearing mycelia. Optimal survival is supported in moist (95–100% humidity), nitrogen-rich soil at temperatures of 37°C or greater and can be found 1 mile below the soil surface.^{409,421} The droppings of chickens, blackbirds, and starlings contain nutrients that promote growth, and, at least in the case of chickens, may contain substances that discourage the growth of competitive organisms. Birds excrete the fungus in droppings yet remain uninfected, probably because of their high body temperature. Bats become infected and excrete the fungus in their guano, which contains substances that encourage fungal growth.^{121,242,392} The migratory behavior of bats has been shown to be associated with genetic variation and both the geographic distribution and the ecotype dispersion of *H. capsulatum*.³⁹³ *H. capsulatum* can remain viable in droppings or other contaminated sites for many years.⁴⁶⁰

Examinations of restriction fragment length polymorphisms of DNA have delineated three broad classes of this fungus that exhibit geographic and possibly clinical differences.^{113,213,414} Class 1 strains are isolated almost exclusively from immunocompromised patients. Class 2 strains are found most frequently in North America, and class 3 strains are found in Central and South America. Individual strains within each class have been examined further with additional nucleic acid–based and genome-wide approaches to reveal considerable genetic diversity.^{193,273,393} Such strain differences are useful for molecular epidemiologic investigations.^{272,391,394,477} Additional investigations using molecular methodology have suggested that genetic differences in the pathogen may underlie clinical differences.^{208,275} Studies have suggested that patients with AIDS may be infected with less virulent, temperature-sensitive variants of *H. capsulatum*.³⁷⁹

Histoplasma duboisii, the cause of African histoplasmosis, is a variant of *H. capsulatum*. *H. capsulatum* var. *duboisii* is indistinguishable from *H. capsulatum* var. *capsulatum* in its mycelial stage; in its tissue phase it appears as thick-walled, oval yeast forms that are 10 to 15 μm in

diameter. Infections caused by *H. capsulatum* var. *duboisii* have been described across central and western Africa, and cases occur along with histoplasmosis caused by *H. capsulatum*.^{160,244}

EPIDEMIOLOGY

Histoplasmosis is almost always acquired when sites contaminated with *H. capsulatum* are disturbed and spores are aerosolized and inhaled. The early understanding of its global epidemiology and clinical signs was skewed by analyses of localized outbreaks after exposure to large inocula. A more accurate picture emerged when skin test epidemiology, environmental cultures, vectors, and analyses of patients' exposures were considered.⁵⁹

Histoplasmosis has been reported worldwide in tropical, subtropical, and, most frequently, temperate areas.²⁶⁵ Most illnesses are sporadic and unassociated with exposure to a specific site or specific activity. They are presumed to result when environmental conditions are conducive to fungal growth and when dry, windy conditions or other events or activities facilitate the aerosolization of spores.

Although early reports emphasized that the infection usually was associated with occupational exposure in primarily rural environments, infection is recognized commonly in urban areas, where it may affect many people.^{194,246,454} Asymptomatic infections are common in children and are usually clinically unrecognized.^{45,164,185} In a highly endemic area, skin test reactivity was 34% in children younger than 2 years of age, 55% between 2 and 4 years of age, and 77% in 10-year-old children.⁴⁷⁹ Rates accelerated in summer.

Regions with high rates of infection are considered endemic. The incidence of infection varies widely in these regions. Localized and very heavily contaminated sites, termed *microfoci*, may be found in which localized, sometimes severe, outbreaks occur. Because the droppings of birds and bats accelerate growth of the mycelial form in the environment, implicated sites have included blackbird and pigeon roosting areas, chicken houses, bat-infested caves,^{22,187,248} attics, chimneys, old structures, and decaying woodpiles and trees. Activities that disturb these areas have been implicated in localized outbreaks.^{185,319} Infections in children have been associated with exploring caves, playing in barns or hollow trees, cleaning abandoned buildings, cutting firewood or decayed tree stumps, renovation of older homes, digging in contaminated sites, excavation or demolition of buildings, cleaning seldom-used fireplaces, and exposure to fungal aerosols that gain access to air duct intakes.^{63,246} An outbreak in Mexico was associated with contact with contaminated compost in potted plants.³⁹⁴

The geographic distribution of *H. capsulatum* skin test reactivity among 275,558 US Navy recruits was studied between 1958 and 1965.^{114,115,253} The highest incidence was found in residents of the Ohio-Mississippi-Missouri, St. Lawrence, and Rio Grande River Valleys. In four states (Arkansas, Kentucky, Missouri, and Tennessee), the percentage of positive adult reactors ranged from 57% to 68%. In the adjacent states (Illinois, Indiana, Ohio, and Oklahoma), reactivity ranged from 50% to 73% among adults in farm areas. Of the other seven states in the endemic area, lifetime prevalence rates exceeding 50% were shown in one or more counties. Epidemiologic studies have not been repeated, and population shifts and changes in land use may alter these patterns. In Latin America,⁶⁰ areas of high prevalence include Venezuela,²⁵⁶ Colombia,^{19,274} Ecuador,²⁹⁹ Brazil,²⁸ Paraguay, Uruguay, and Argentina.⁷⁹

Analyses of point-source and sustained outbreaks offer some means of assessing the epidemiology and clinical spectrum of infections. An outbreak in Indianapolis, Indiana, affected an estimated 100,000 persons within a 400-square-mile area and lasted nearly 1 year.⁴⁵³ Illnesses were identified in 435 persons (including 49 children <15 years), and disseminated disease developed in 46. Persons 15 to 34 years of age were more likely to become infected than were other age groups. An equal sex distribution of infections occurred before puberty; male patients predominated in a 3:1 ratio in older persons. Localized outbreaks related to high-risk sites and activities are well documented.^{34,350,408} In one analysis, 105 reported outbreaks comprising 2850 cases were documented in the United States during 1938 to 2013.³² In 70 outbreaks with complete data, 51% of cases occurred among children younger than 18 years of

age, with a majority of cases associated with two large school-related outbreaks. Indiana had the most reported cases (790).

Infections acquired during travel and/or migration to endemic regions are being reported more frequently.* Infections acquired in areas not recognized as endemic, such as occurred in college students whose only known common exposure was vacationing at a hotel in Mexico,²⁷⁰ require consideration of the diagnosis in patients with compatible clinical findings.^{14,52,57,349} Isolated cases may not be associated readily with high-risk activities. Rarely, infections occur in nonendemic areas and may result from reactivation of quiescent infection in patients who become immunosuppressed.^{15,48,189,403}

Vertical transmission, in an area not endemic for histoplasmosis, of both disseminated histoplasmosis and HIV infection was reported in the 5-week-old infant of a mother with both HIV infection and disseminated histoplasmosis.¹¹ In another case, mother-infant transmission with resulting dissemination was documented following exposure to tumor necrosis factor- α (TNF- α) blocker therapy.⁶² Although a case of sexual transmission that resulted from exposure to mucosal lesions of a patient with disseminated histoplasmosis has been described,³⁷⁰ human-to-human transmission is exceedingly rare. Transmission has been confirmed, with the use of molecular typing methodology, in the recipients of two cadaveric organs from a donor who had resided in an endemic area.²³⁴ Although various wild and domestic animals may become infected, transmission of histoplasmosis to humans does not occur.⁴⁶ Infection of an infant after exposure to a pillow that contained contaminated feathers has been reported.⁵⁸ Infections caused by inoculation of contaminated material from either the environment or laboratory accidents are also rare.⁵⁰

PATHOPHYSIOLOGY

H. capsulatum has unique interactions with human macrophages, dendritic cells, and neutrophils, the outcomes of which contribute to its success as a pathogen.^{284,286,365} Key are its abilities to infect and gain access to macrophages; alter the intracellular environment, thereby allowing the organism to survive, replicate, and disseminate; remain viable during clinically unapparent infection; and become reactivated when host immune factors permit.^{55,95,117,153,469} Inhalation of fungal spores induces a brisk innate immune response that is followed by an acquired immune response after about 2 weeks. During these events, the fungus induces an orderly modulation of the host inflammatory and cytokine and chemokine responses.²²⁰ Production of cytokines begins within 24 hours of primary infection and continues for approximately 3 weeks, bridging both the innate and acquired immune responses. Successful clearance of the infection depends primarily on the functional integrity of cellular immunity.^{21,206,293,329,481} The clinical manifestations and outcome are determined by this complex interplay of events.

The length of the incubation period of histoplasmosis varies inversely with the size of the inoculum, the integrity of the host immune response, the presence of immunity from previous infection, and strain-related differences in fungal virulence.^{116,150,218} Although the range of incubation periods is reported to be 1 to 3 weeks in nonimmune hosts, it has been based largely on data from point-source outbreaks in which the time of the event leading to exposure is readily determined. In these settings, the size of the infecting inocula is probably larger, however, than those resulting in sporadic infections.⁵⁹ Because most infections occur sporadically and either are asymptomatic or result in nonspecific and self-limited flu-like illnesses that are not diagnosed, the upper range may be longer. In patients who retain specific cellular (protective) immunity from previous infection, reexposure results in milder symptoms and shorter incubation periods, usually 4 to 7 days.⁵⁹ A very few otherwise normal infants as well as persons of any age with primary or acquired cellular immune dysfunction are more likely to experience symptomatic illness after exposure.¹⁵⁰ In the most common situation, pneumonitis develops after inhalation of *H. capsulatum* microconidia or mycelial fragments.²⁹ Because of their smaller size, microconidia enter terminal alveoli and, within 2 to 3 days, germinate and convert to yeast forms. Dimorphism

appears to be a major determinant of virulence; chemical blockage of the transition has been shown to impair virulence.^{179,290} Progress in understanding the molecular cell biology and genetics of the mold-to-yeast transition has been reviewed.¹⁸⁶

In the first week, a neutrophil response occurs at the site of the infection; it is followed in approximately 2 weeks by the accumulation of helper T lymphocytes and macrophages.³²¹ The yeast forms attach to integrins of the CD11/CD18 group of cell surface receptors and enter neutrophils^{361,365} and macrophages.^{51,389} This process enables the organism to evade the host oxidative burst response associated with host-directed opsonophagocytosis.⁴⁶⁸ Human neutrophils possess fungistatic activity that resides within azurophilic granules.^{47,285} Although neutrophils appear to play a role in the primary immune response, depletion of neutrophils in a systemic model of secondary infection did not alter the course.⁴⁸³ Phagocyte-produced reactive oxygen species participate in the immune response, whereas superoxide dismutase facilitates pathogenesis by detoxifying host-derived reactive oxygen, thereby enabling survival of *Histoplasma*.⁴⁷⁶

The yeast forms seem to have a competitive advantage within the membrane-bound vacuoles of macrophages,^{283,282} and the asylum seems to protect it from pulmonary collectin-mediated killing.²⁵⁷ Both fungal growth and virulence are exquisitely sensitive to the availability of iron.¹⁷⁸ Zinc deprivation is also thought to be a host defense mechanism used by macrophages in a mouse model.⁴⁶⁶ Lysis of infected cells releases additional yeasts and results in infection of increased numbers of macrophages. During this period of fungal sequestration and replication, lymphohematogenous dissemination distributes yeast from the lungs to the reticuloendothelial system and to other organs.

Although infection usually results in a brisk antibody response, humoral immunity does not contribute substantially to primary or secondary immunity.^{251,290,351} Human dendritic cells that reside in the lung serve to link the innate and adaptive immune responses. Because they are more efficient antigen-presenting cells than alveolar macrophages, dendritic cells use the fibronectin receptor, phagocytose and rapidly degrade the organism, present *H. capsulatum* antigen for lymphocyte proliferation, and facilitate the induction of cell-mediated immunity.^{143,283,388} Dendritic cells also have been shown to cross-present exogenous antigen through uptake of apoptotic macrophage-associated fungal antigens.²³⁷ Destruction of yeast within human dendritic cells is an important role within the innate immune response.²⁸³ Conidia transformation into yeast-like forms does not take place within dendritic cells.²⁸⁶

After they participate in the innate immune response, several endogenous cytokines,²²⁰ induced by the development of cellular immunity,²⁸³ activate macrophages, which then function as primary cellular effectors that control the infection.^{95,282,365} Cytokines that play key roles in the resolution of primary or secondary infection (protective immunity) include TNF- α , interferon- γ (IFN- γ),^{10,76,224,413} interleukin (IL)-4,⁹⁴ IL-12,^{56,484,485} IL-1,⁹⁹ and granulocyte-macrophage colony-stimulating factor.^{10,98,376}

In addition to macrophages, specific T-cell subpopulations also are capable of killing *H. capsulatum*. CD4⁺ cells have been shown to be essential for fungal clearance in mouse models.^{93,147,236} This comports with observations showing that the risk for severe histoplasmosis in adults with HIV infection increases when the CD4⁺ count is lower than 200/ μ L.⁴³⁶ CD8⁺ cells also mediate immunity, but their contribution is not as significant as that of CD4⁺ cells.^{236,237,482} Natural killer cells participate to a limited degree in the immune response in immunocompetent animals and play a more substantial role in animals depleted of T cells.^{283,308}

In immunocompetent hosts, cellular immunity is suppressed early in the course of histoplasmosis, especially in disseminated histoplasmosis of infancy.^{21,72,293,312} Cellular immune function returns to normal after 4 to 6 weeks of treatment. T-cell immunity develops 10 to 21 days after exposure, and splenic suppressor T-cell numbers decrease, whereas helper T-cell numbers increase.²¹ In one report, lymphoproliferative responses approached normal in patients with CD4⁺ counts greater than 500 cells/ μ L; lymphoproliferative responses and IFN- γ production were depressed in patients with CD4⁺ counts of 200 to 500 cells/ μ L.⁴⁰⁷ In addition to having defective cellular immunity resulting from decreased numbers of CD4⁺ cells, the macrophages of patients with HIV infection have impaired ability to control *H. capsulatum*. This results from a profound defect in

*References 15, 16, 17, 49, 123, 137, 188, 203 to 205, 270, 289, 304, 364, 420.

the ability of these macrophages to recognize and bind to yeast and from permissiveness for intracellular fungal growth.⁶⁵ The HIV envelope glycoprotein gp120 seems to play a role in inhibiting phagocytosis of *H. capsulatum* by macrophages, but it is not responsible for the capacity for accelerated growth of yeast within macrophages.⁶⁶

PATHOLOGY

With the exception of patients who have severe, progressive, disseminated infection, particularly patients with preexisting primary or acquired cellular immune dysfunction, histopathologic findings in histoplasmosis are characterized by granulomatous inflammation, usually in association with caseating and noncaseating granulomas. The mature granuloma serves both to localize inflammation and to inhibit fungal growth. Another potential and clinically important outcome of this microenvironment is late reactivation of the infection in the event of acquired immune dysfunction.^{175,410}

Granulomas appear after the development of an effective acquired immune response; the cellular elements consist primarily of mononuclear phagocytes and lymphocytes, largely T cells. Langerhans giant cells often are present; and typical yeast forms occasionally, but not consistently, are visible within macrophages. Inflammation ultimately progresses to fibrosis and often is accompanied by calcification.¹⁵⁰ The rate of calcification is age dependent, and it may occur within months in children and over several years in adults.^{150,383} Exuberant granulomatous inflammation or fibrosis, or both, can result in obstruction or dysfunction of adjacent mediastinal or, less commonly, abdominal structures. In areas endemic for histoplasmosis, old granulomas in the lung, bone marrow, or other sites may be seen as incidental findings, the significance of which depends on clinical assessment. Yeasts are hardly ever observed in histologic sections of extensive fibrosis in late histoplasmosis.

In patients with acute progressive manifestations of histoplasmosis, especially patients with preexisting cellular immune dysfunction, or in otherwise normal infants, the inflammatory response is impaired, and granuloma formation is poor.^{124,268} In these instances, extensive parasitization of macrophages by yeasts occurs, and organisms may be seen readily in various reticuloendothelial structures, especially the bone marrow, and sometimes within leukocytes in the peripheral blood.²⁹³ Many other organ systems are often involved. The histopathologic findings in central nervous system (CNS) infection consist of granulomatous basilar meningeal and vascular inflammation, perineural inflammatory changes in cranial nerves, and the presence of many organisms at the periphery of mass lesions.⁴²⁹ In disseminated infections, the adrenal glands frequently are affected.^{24,387} A spectrum of pathologic abnormalities of the gastrointestinal tract may also occur.^{23,78,223,305,334}

CLINICAL MANIFESTATIONS

Approximately 95% of infections caused by *H. capsulatum* occur in healthy persons and either are asymptomatic or cause brief, self-limited illnesses with no sequelae. The only residual findings are the incidental radiographic demonstration of typical granulomas in the lung parenchyma and calcifications in the hilar mediastinal lymph nodes or spleen (Fig. 204.2). In immunocompetent hosts, the size of the inoculum probably is the principal determinant of whether infection is accompanied by clinical symptoms. After exposure to small inocula, only 1% of persons develop symptoms, whereas after heavy exposure, 50% to 100% will become ill.⁴²¹ Additionally, the symptoms that develop are more severe in persons exposed to large inocula. Severity may be reduced in persons with preexisting immunity derived from previous infection. Protection is incomplete, however, and severe disease can occur after reexposure to a large inoculum.

A crucial determinant of susceptibility and disease severity also is host dependent. Persons with primary or acquired disorders of cellular immunity and otherwise normal infants younger than 1 year of age have a disproportionately high risk for developing symptoms after exposure. These groups are at far greater risk for progression of early dissemination. The precise factor or factors that predispose to a higher risk for progressive dissemination in infections acquired during infancy have not been determined.^{231,293,328}

FIG. 204.2 Computed tomography scan of an asymptomatic previously healthy adolescent girl undergoing evaluation for idiopathic scoliosis is found to have multiple areas of lymph node calcifications secondary to histoplasmosis.

As with other endemic mycoses, histoplasmosis begins as acute inflammatory pneumonitis, undergoes self-limited or progressive dissemination, and requires an effective host immune response for its control. Clinical manifestations (Box 204.1) vary because they result from any or all of the following: the nonspecific systemic effects caused by the infection, symptoms resulting from either the primary inflammatory focus or perturbation of function of anatomic structures adjacent to primary sites of inflammation, hypersensitivity phenomena resulting from the acquired immune response, symptoms caused by hematogenously infected sites, life-threatening multisystem symptoms resulting from progressive parasitization of the reticuloendothelial and other organ systems, symptoms caused by chronically progressive forms of pneumonitis or dissemination, or exacerbation of quiescent disease. Recognition, confirmation of the diagnosis, and selection of prudent therapeutic options require understanding of these diverse clinical manifestations. Aside from patients with known preexisting conditions or those receiving therapy that impairs immune function, all patients with serious disseminated disease, persistent antigenuria after completion of therapy, relapse, or recurrent infections should undergo comprehensive assessment of immune function.

Pulmonary Histoplasmosis

The most common symptoms of acute primary histoplasmosis encompass a spectrum of respiratory and systemic complaints of varying severity.^{262,432} Eighty percent of infections that are accompanied by symptoms are mild, undifferentiated, flulike illnesses with cough, myalgia, headache, and variable low-grade fever. Symptoms usually are self-limited and resolve in 3 to 5 days.⁴²¹ In patients with more significant fungal exposure, fever is present, and symptoms can include headache, myalgia, chills, persistent cough, and nonpleuritic chest pain.¹⁵⁰ Acute illness may persist for as long as 2 weeks and be associated with nausea, asthenia, weight loss, or fatigue. These manifestations are also self-limited, although fatigue and weight loss improve slowly after the fever resolves. In primary infections that last more than 2 weeks, fever persists and is often accompanied by greater weight loss, chills, night sweats, fatigue, or chest pain. The chest pain that occurs in histoplasmosis typically is nonpleuritic. It may be substernal, posterior, or lateralized, it usually is brief in duration, and it recurs frequently. This pattern of chest pain may last from a

BOX 204.1 Clinical Manifestations of Histoplasmosis

- Asymptomatic infection
- Pneumonia
- Progressive disseminated infection (HIV, immunocompromise, infancy)
- Mediastinal lymphadenopathy
- Cavitory pneumonia^a
- Asthma-like illness
- Pleural effusion or granulomatous pleuritis^a
- Obstruction or dysfunction of contiguous mediastinal structures (bronchi, esophagus) by granulomatous inflammation of lymph nodes (mediastinal granuloma)
- Isolated cervical or supraclavicular lymphadenopathy^a
- Superior vena cava syndrome^a
- Mediastinal fibrosis^a
- Vocal cord granuloma
- Vocal cord paralysis
- Hemoptysis
- Broncholithiasis with lithoptysis^a
- Chylothorax^a
- Diaphragmatic weakness or paralysis
- Esophageal diverticulum or fistula
- Pericarditis
- Erythema nodosum
- Meningitis or focal cerebritis^a
- Arthritis or arthralgias
- Parotitis
- Nephrocalcinosis
- Interstitial nephritis^a
- Hypercalcemia
- Gastrointestinal tract ulceration or hemorrhage
- Gastrointestinal tract pseudomalignancy
- Crohn disease–like illness
- Biliary obstruction^a
- Ocular histoplasmosis, choroiditis^a
- Endocarditis^a
- Adrenal mass^a

^aRare in children.

HIV, Human immunodeficiency virus.

week to several months.¹⁵⁰ Wheezing may be an early symptom.^{53,419} Hepatosplenomegaly occasionally is present, although its occurrence should raise suspicion of the early onset of progressive dissemination. In these prolonged illnesses, resolution without treatment may occur, but with the safe and effective oral antifungal agents available, most experts recommend treatment.

After development of the respiratory complaints that accompany primary infection, rheumatologic syndromes may be seen within several months of infection. They usually consist of erythema multiforme,²⁶⁷ erythema nodosum (Fig. 204.3),^{150,241,267,303,366} acute migratory polyarthritis, or any combination of these conditions.^{74,344} Although histoplasmosis-induced erythema nodosum is seen during childhood and adolescence, arthritis is uncommon. The rheumatologic symptoms are immune mediated and usually self-limited or respond to mild antiinflammatory therapy.

Finally, in acute primary infections that occur after exposure to a large inoculum of spores, the resulting diffuse pneumonitis may be associated with severe symptoms, particularly dyspnea or adult respiratory distress syndrome early in the infection. In these instances, the ordinarily self-limited early dissemination has a high risk of becoming progressive, and treatment is required.

Various symptoms may result from complications arising from intrathoracic or, less commonly, intraabdominal lymphadenitis caused by *H. capsulatum*. One of the most problematic, often termed mediastinal

FIG. 204.3 Erythema nodosum in an adolescent boy with pulmonary histoplasmosis.

lymphadenitis, is an acute primary infection accompanied by fever, weight loss, and a mediastinal mass visible on chest radiograph. The presence of mediastinal lymphadenopathy in the absence of any recognized clinical symptoms often requires a definitive diagnosis to exclude a neoplasm, especially lymphoma.^{134,279} Pediatric series that have examined the definitive diagnosis of such manifestations have found rates of histoplasmosis to range from 1% to 57%, a discrepancy best explained by considering whether the study population lived in an endemic region.^{40,134,418,470} In a highly endemic region, middle mediastinal masses were more likely to be features of histoplasmosis if the *Histoplasma* complement-fixation (CF) titers were 1:32 or greater, thereby obviating need for biopsy to determine likelihood of lymphoma.¹³⁴

Complications of acute primary histoplasmosis may be seen when granulomatous lymphadenitis results in inflammation, compression, or obstruction of contiguous structures within the thorax; this manifestation occasionally is termed mediastinal granuloma.^{339,404} Structures most commonly affected are, in decreasing order of frequency, the bronchi, trachea, pericardium, pulmonary vasculature and great vessels,¹⁹⁶ lymphatics, esophagus (Fig. 204.4),^{112,381} nerves, and endovascular infections of prosthetic endografts or valves.^{173,195} Symptoms include bronchial compression or obstruction, or both, which sometimes are associated with the following: distal pneumonitis; pericarditis; pulmonary infarction; esophageal diverticula,³⁸¹ fistula formation, or dysmotility, alone or in combination; tracheoesophageal fistula formation; phrenic or recurrent laryngeal nerve palsy; or, in endovascular infections, embolic phenomena. Presumably because of their more pliable airways, children are more susceptible than adults to tracheobronchial compression as a result of encroachment by enlarged lymph nodes.¹³⁶

In highly endemic regions, histoplasmosis is the cause of 25% of acute pericarditis cases; approximately one-fourth of patients have symptoms of cardiac tamponade.⁴²² In almost all instances, pericardial effusion results from inflammation caused by infected lymph nodes adjacent to the pericardium and not by frank fungal pericarditis.⁴⁷⁵ Rarely, contiguous adenitis or broncholiths erode through the pericardium and cause fungal contamination of the pericardial space.^{150,475} The pericardial fluid is exudative, bloody, and almost always sterile.⁴⁵³ Most patients with *Histoplasma* pericarditis quickly improve with

FIG. 204.4 Esophagogram of a young child with difficulty in swallowing and weight loss. Compression of the esophagus secondary to a large mediastinal granuloma is evident.

administration of nonsteroidal antiinflammatory drugs, and neither acute drainage nor pericardiectomy is needed.

Pleural effusions occur very rarely in children with histoplasmosis, and, similar to pericarditis, seem to result from pleural inflammatory reactions to adjacent granulomas; results of cultures of pleural fluid are negative.³²⁷ Chylothorax caused by extrinsic compression of the thoracic duct by histoplasmosis-induced lymphadenitis was reported to occur in a 3-year-old child.⁴⁰⁴ Broncholithiasis may result from calcifications that erode through bronchi but rarely occurs in children.³⁵ Lower cervical or supraclavicular adenitis is an infrequent manifestation of histoplasmosis and usually is seen in association with mediastinal involvement.²⁵⁸ Lymphadenitis occasionally affects intraabdominal lymph nodes and has been reported to cause biliary tract obstruction in children.^{7,309,334}

Subacute or chronic manifestations of intrathoracic histoplasmosis may occur in children, although they most commonly affect older adults. Of these entities, diffuse mediastinal fibrosis may affect adolescents, albeit infrequently. In these rare instances, granulomatous inflammation progresses to dense fibrosis and may cause stenosis, obstruction, or malfunction of contiguous critical mediastinal structures. Although symptoms are similar to those caused by active granulomatous inflammation that impairs the function of these structures, the fibrosis is progressive and irreversible and responds to neither antifungal therapy nor antiinflammatory agents.²⁴⁵ Common complications include the superior vena cava syndrome or stenosis or obstruction of the trachea, bronchi, pulmonary artery, or esophagus. Late constrictive pericarditis has been reported in adults with *Histoplasma* pericarditis,^{150,471} but it is a rare finding in children.

Additional late complications of intrathoracic histoplasmosis are seen primarily in adults and include pulmonary histoplasmoses (lung nodules), which are granulomas in the peripheral lung fields that become encased in dense fibrous tissue, often with concentric layers of calcification. These may enlarge over several years and cause symptoms of a mass lesion or may manifest as an isolated pulmonary mass.¹⁵² Endobronchial lesions may result in stricture, obstruction, or hemoptysis and mimic bronchogenic neoplasms.^{341,345}

FIG. 204.5 Cavitary lung disease caused by histoplasmosis in a 16-year-old previously healthy boy presenting with cough and hemoptysis. Sputum was positive for *Histoplasma capsulatum*.

Cavitary (also termed chronic) pulmonary histoplasmosis is rarely observed in children.^{33,106} In an analysis of risk factors for cavitary disease in an outbreak estimated to have involved 150,000 persons, only 2 in 170 patients with cavitary disease were younger than 19 years of age (Fig. 204.5).⁴⁵⁶ Cavitary disease was seen primarily in adults with chronic obstructive pulmonary disease. Symptoms include low-grade fever, productive cough, weakness, weight loss, and fatigue. Early pulmonary findings consist of apical interstitial pneumonitis that eventually progresses to fibrosis, cavitation, and gradual spread to uninvolved areas of the lung.⁴⁴⁷ If chronic histoplasmosis is untreated, the disease is fatal.²¹¹ Disseminated infection has been reported to develop in approximately 80% of patients with this disorder.³⁴⁷

Primary Cutaneous Histoplasmosis

Numerous reports describe immunocompetent patients who present with mucosal, corneal,³⁹⁹ or cutaneous ulcerated lesions that show characteristic pathologic changes and morphologic and cultural documentation of *H. capsulatum* and resolve without treatment.^{83,138,295,342,370,412,474} These lesions have been considered to be primary, localized infections.³⁹⁷ Aside from several cases that reasonably may be attributed to documented instances of direct inoculation,^{221,370} many of these reports fail to provide sufficient evidence to exclude low-grade, chronic dissemination with histoplasmosis.^{8,122}

Progressive Disseminated Histoplasmosis

Progressive disseminated histoplasmosis (PDH) occurs most frequently in immunodeficient patients and patients at the extremes of age.^{151,231,293,447} The clinical entity is defined as an illness that is accompanied by active replication of *H. capsulatum* in multiple organ systems. Symptoms are prolonged and usually last for more than 3 weeks. Laboratory evidence of dissemination may include the following: anemia, thrombocytopenia, or leukopenia, or a combination of these; persistent antigenuria or antigenemia, or both; demonstration of granulomas in extrapulmonary tissue; histopathologic demonstration of compatible yeast; or growth of the fungus in culture. The intense exposure to a large fungal inoculum results in severe primary infection that overwhelms the host's ability to mount an effective cellular immune response, thus allowing the usually self-limited primary dissemination to progress.

Distinct clinical presentations of PDH in adults permit subclassification into acute, subacute, and chronic forms. In contrast, PDH in children

occurs almost exclusively as an acute, progressive, life-threatening infection.^{231,293,328} Most of these infections develop in immunocompetent infants younger than 1 year of age or in children with acquired or primary cellular immunodeficiency. Rarely, PDH occurs in an immunocompetent child, usually in association with exposure to a large fungal inoculum.⁹⁰ Transplacental infection has been reported to occur in infants of women with PDH complicating HIV infection.⁴⁵⁹

PDH may result from exogenous exposure of a susceptible or immune host or from reactivation of endogenous quiescent foci of infection. Although reactivation of infection may occur in an immunosuppressed host,^{190,403,410} epidemiologic data in immunosuppressed persons who reside in areas highly endemic for histoplasmosis favor a new episode of exogenous exposure as the most common mechanism. Supporting evidence consists of observations showing that rates of PDH in immunocompromised patients increase only during periods in which infection rates increase in the general population and do not increase in interepidemic periods.^{314,357,360,407} Using the results of histoplasmin skin testing obtained at the time of diagnosis of malignancy in a large cohort of children, Hughes¹⁸⁴ found that skin test reactivity was absent in all children in whom PDH subsequently developed and that in none of those known to be skin test positive at the time of diagnosis of neoplastic diseases did PDH develop later.

Progressive Disseminated Histoplasmosis of Infancy

PDH of infancy usually affects children younger than 1 year of age.^{231,293} It usually is a subacute illness in which symptoms often are reported to have been present for 1 to 12 weeks before the patient undergoes an initial evaluation; as the disease progresses, patients eventually become profoundly ill and usually die unless treated. Early symptoms include variable fever, failure to thrive, and hepatosplenomegaly in almost all instances.³⁸⁰ Pallor, cough, tachypnea, oropharyngeal ulcerations, lymphadenopathy, gastrointestinal bleeding, or hemorrhagic skin lesions may develop. Abnormalities that are seen frequently in laboratory studies, and inexorably worsen, include anemia, thrombocytopenia, leukopenia,^{151,231,328} disseminated intravascular coagulopathy, and marked depression of immunoregulatory cells.^{72,293} These abnormalities reflect the overwhelming fungal parasitization of the reticuloendothelial system and often mimic the presenting signs of a lymphoreticular malignant disease.² The chest radiograph may show signs of focal pneumonitis, mediastinal adenopathy, or miliary disease, but more than 50% of chest radiographs are normal at the time of diagnosis. Anatomic sites commonly affected include the spleen, liver, bone marrow, lymph nodes, gastrointestinal tract, and adrenal glands. Abnormalities in the cerebrospinal fluid (CSF) were found in 62% of a series of infections in Costa Rican infants.²⁹³

PDH of infancy was uniformly fatal before effective antifungal agents became available,²³¹ but survival rates are now excellent. In a series of Costa Rican children that included some infants with malnutrition, 90% of patients treated with amphotericin B survived. In our experience, survival has been 100% in an Indiana series of PDH of infancy.

Progressive Disseminated Histoplasmosis in Immunocompromised Hosts

Immunocompromised persons, including those with either a preexisting medical condition or therapy that has depressed cellular immunity, are at risk for progressive dissemination if they acquire histoplasmosis. Common predisposing conditions include AIDS,⁶⁴ primary immunodeficiency disorders,^{180,353,481} iatrogenic immunosuppressive therapy for reticuloendothelial malignant diseases,¹⁸⁴ organ transplantation,^{158,259,288} rheumatologic disorders,¹⁶⁶ and chronic renal failure.¹⁹¹ Severe PDH infections have been recognized in patients treated with TNF- α antagonists for inflammatory disorders.^{166,467} This effect seems to be associated most closely with the use of infliximab, a TNF- α inhibitor.^{108,118,133,229,233,411}

The most common initial symptom is persistent fever, usually without localizing symptoms and unassociated with toxicity. As the illness evolves, fever persists, and liver and spleen enlargement may occur. Laboratory abnormalities include progressively worsening anemia, leukopenia, and thrombocytopenia; disseminated intravascular coagulopathy may ensue. The chest radiograph may be normal. *Histoplasma* antibody assay results

FIG. 204.6 Diffuse lung disease secondary to disseminated histoplasmosis in an adolescent girl with immunoglobulin A nephropathy treated with immunosuppressive therapy.

usually are negative, and the diagnosis is confirmed reliably by using the *Histoplasma* antigen assay of urine or serum.^{2,184}

Another common symptom complex consists of respiratory complaints and tachypnea. In these instances, persistent fever is followed in several days by dyspnea. Chest radiographs, although occasionally normal at the onset of symptoms, show diffuse interstitial infiltrates that progressively worsen (Fig. 204.6).² Hypoxemia usually accompanies the symptoms and is progressive. This clinical complex is not specific for histoplasmosis and may be indistinguishable from those caused by *Pneumocystis jiroveci*, cytomegalovirus, various viral respiratory pathogens, other opportunistic fungi, and bacterial septicemia.

A subacute form of PDH is seen primarily in adults,⁴⁴⁷ although in one report of 19 cases it was found in seven infants and one child.¹⁵¹ The principal clinical features that distinguish the subacute from the acute form of PDH are a history of more prolonged symptoms at initial evaluation, a higher frequency of focal lesions, less pronounced fever, and fewer hematologic abnormalities in the subacute illness. Early complaints are nonspecific and may be present for 1 to 6 months; malaise and weight loss occur frequently. Hepatosplenomegaly is seen almost uniformly, and intestinal ulceration,²⁰⁶ sometimes with perforation, occurs commonly.

Gastrointestinal histoplasmosis has protean manifestations, including perforation,²⁰¹ that may occur in association with mediastinal histoplasmosis²⁰² or in the setting of PDH.²⁰¹ An autopsy study of 93 adults with AIDS in an endemic region identified gastrointestinal histoplasmosis in 12% of cases.¹⁶¹ The terminal ileum often is involved, and findings may mimic those of Crohn disease.^{61,382} Colonic lesions may result in bleeding or obstruction,^{177,367} and they may mimic neoplasms.²²⁸ Isolated colonic lesions without evidence of dissemination are rare.²¹⁶ Oropharyngeal ulcerations often occur and are large and deep and can mimic neoplasms.^{18,122,151} Seventy-five percent of patients have adrenal involvement, which sometimes is unilateral.³⁸⁷ Adrenal insufficiency occurs less frequently but is reported in 15% to 50% of adults.^{10,151,156,225,330,331}

³⁷⁷ CNS infections are seen occasionally and may manifest as chronic meningitis, focal mass lesions, or focal areas of cerebritis. Reports suggest that patients with *STAT3*-mutated hyper-immunoglobulin E (Job) syndrome may be at high risk of disseminated infection involving the CNS and gastrointestinal systems.^{292,382} Endovascular infections occur and may affect normal or native valves. The aortic or mitral valves or prosthetic valves most commonly are affected.^{9,36,67,119,139,173} Valvular disease seen is typical of fungal endocarditis, with large vegetations and a high frequency of embolic phenomena.¹⁰¹ Valve replacement was common.³³⁸

Vaginal and penile ulcerations, soft tissue nodules, recurrent pan-niculitis, tenosynovitis, carpal tunnel syndrome, osteomyelitis and arthritis, enteropathies, immune hemolytic anemia, and epididymitis all have reported.^{200,212,215,301,322,344,370,384,419} Although the pace of subacute PDH is slower than that of acute PDH, the subacute form is nonetheless fatal in 2 to 24 months if untreated.¹⁵¹

Chronic disseminated histoplasmosis is seen almost exclusively in adults, usually in association with cavitory pulmonary lesions.¹⁵¹ Oropharyngeal ulcers are accompanied by chronic, mild, intermittent constitutional symptoms. A chronic relapsing disseminated form of the disease was described in two younger patients, 9 and 20 years old, with chronic mucocutaneous candidiasis^{124,268,310} and in a child with IFN- γ receptor-1 deficiency.⁴⁸¹

Progressive Disseminated Histoplasmosis in Human Immunodeficiency Virus–Infected Patients

Before the development of effective antiretroviral therapy, disseminated infection developed in more than 90% of HIV-infected adults who acquired histoplasmosis.⁴³⁶ In 1988, less than 0.5% of adult patients with AIDS had disseminated disease.¹⁵⁴ In endemic areas, it has been reported in approximately 5% of patients,^{170,263} as well as in 21% to 53% of patients during epidemic periods.^{39,424,436,455}

In a multivariate analysis of risk factors for the development of histoplasmosis in HIV-infected adults residing in endemic areas, receipt of antiretroviral therapy and triazole drugs was associated independently with decreased risk.^{170,263} One study found the risk to be increased with positive baseline serologic findings, CD4⁺ cell counts lower than 150/ μ L, and exposure to chicken coops.²⁶³ Risk factors for death in two large cohorts of adults were also determined.^{84,101,430} Mortality rates were greater in HIV-infected patients with PDH who were treated with antifungal therapy compared with HIV-negative patients with PDH; in HIV-positive patients receiving highly active antiretroviral (HAART) therapy in association with antifungal therapy, clinical outcomes were similar to those of patients with PDH unassociated with HIV infection.⁴⁰⁰ Comparable studies have not been done in children. In Arkansas, a highly endemic area, histoplasmosis was the AIDS-defining illness in 8% of 40 children who acquired HIV infection in the perinatal period.³⁶³ Histoplasmosis in this population is occasionally seen in nonendemic regions, perhaps because of reactivation of quiescent foci of infection.^{17,123,352,356} An adult series found that patients with AIDS complicated by disseminated histoplasmosis had a substantially higher mortality rate (32% vs. 14%) than did HIV-infected patients with other opportunistic infections.⁸⁶

In HIV-infected adults with disseminated histoplasmosis, early symptoms often are nonspecific; prolonged unexplained fever and weight loss are seen almost uniformly, and respiratory complaints occur in approximately one-half of patients.^{165,198,356,436} Features are not distinctive, and in areas in which *Talaromyces marneffei* (formerly known as *Penicillium marneffei*) also is endemic, clinical, laboratory, and radiographic findings often overlap.^{227,269} In adults, initial chest radiographs are normal in approximately 40%, diffuse interstitial or reticulonodular infiltrates are seen in approximately 50%, and localized lesions are noted in approximately 5%. Diffuse abnormalities may appear during treatment of patients whose chest radiographs initially were normal.³⁵⁶

Gastrointestinal symptoms, including perforation and those caused by partial obstruction, are reported commonly and usually are nonspecific; abdominal pain, weight loss, and diarrhea occur in 50% to 70% of patients.^{23,169,171,202,223,367,385} Coinfections do occur.^{3,317} Enlargement of the liver and spleen occurs in approximately 25% of patients. Ten percent of patients are initially gravely ill with signs of a septic shock–like syndrome.⁴³⁶ Mucocutaneous lesions occur in approximately 10% of adult patients and include nonspecific maculopapular rash, papules, nodules, pustules, ulcerative lesions, acneiform lesions, mucosal ulcers, and vegetative plaques.^{18,129,130,167} Lesions may mimic those of secondary syphilis,³⁰⁷ and histopathologic examination of skin biopsy specimens often is diagnostic. The frequency of skin lesions in a cohort of Brazilian adult patients with disseminated infection was 66%.²⁰⁷

CNS involvement, including meningitis, encephalitis, and focal brain lesions, occurs in approximately 18% of patients with PDH complicating HIV infection.^{12,13,39,197,250,356,429} Symptoms include headache, encephalopathy, or complaints arising from focal neurologic abnormalities.

Published reports of histoplasmosis complicating HIV infection in children are few; in four HIV-infected children in Indiana, fever was present in all, and cutaneous lesions were absent; hepatosplenomegaly was found in one child, and an abdominal mass caused by an infected abdominal lymph node was seen in one child.

With the widespread use of HAART for treating advanced HIV infections, an immune reconstitution inflammatory syndrome has been described.^{1,85,278,368} The immunopathogenesis is presumed to result from interaction between HAART-induced improvement of host immune function and residual microbial antigens.^{239,340} *H. capsulatum* is among other granuloma-inducing pathogens reported to induce immune reconstitution inflammatory syndrome.^{1,43,306,368}

Central Nervous System Infection

CNS manifestations occur in 5% to 10% of adults with PDH, but they also may occur as chronic meningitis without other signs of apparent dissemination.^{34,217,429,452} Clinical manifestations are varied and include chronic meningitis and arachnoiditis, hydrocephalus, focal parenchymal lesions, cerebellar ataxia, cranial nerve neuropathy, vasculitis, stroke, and diffuse encephalitis. Isolated meningitis in immunocompetent adults has been associated with presenting signs that include headache, signs of meningeal irritation, and mental status changes.³⁵⁹ Meningitis is seen in association with disseminated infections in children, especially if acquired during infancy.²⁹³ Isolated meningitis is extremely unusual in an immunocompetent child. Isolated or multiple focal lesions affecting the brain^{25,172} or spinal cord,¹⁸¹ stroke syndromes,^{75,287} and encephalitis constitute the balance of manifestations. Meningitis has been reported to occur years after apparent total resolution of PDH.^{43,399} This may result from failure of antifungal agents to penetrate the CNS compartment sufficiently to eradicate the infection.^{25,400,429} Symptoms of meningitis often are present within 6 months of diagnosis but have been reported to be present for 7 years.¹⁴⁰ Commonly associated symptoms include headache, altered level of consciousness, confusion, and cranial nerve deficits in 28% to 56% of cases.⁴²⁹

Diagnosis is problematic in patients with histoplasma meningitis and no associated manifestations of localized or disseminated infection.³⁴⁸ It is suspected ante mortem in only 40% of cases. A case was reported with the onset of symptoms 4 years before the diagnosis was confirmed.³⁴ Symptoms and findings often mimic those caused by other granulomatous infections, sarcoidosis,⁴²⁹ cerebral vasculitis,¹⁹⁷ or conditions leading to hydrocephalus. CSF findings are nonspecific and include mild pleocytosis, elevated protein, and depressed glucose concentration.³³² The diagnosis is confirmed by isolating *H. capsulatum* from CSF, detecting *Histoplasma* antigen or antibody in CSF, or identifying the organism in non-CNS sites. Although the specificities of culture and antigen methodologies are high, the sensitivity is variable. CSF antigen sensitivity is 38% in non-HIV-infected patients and 67% in HIV-infected patients. CSF antibody is present in 80% to 89% of cases; cross reactions with *Cryptococcus* occur in 28% of cases.⁴⁵²

Presumed Ocular Histoplasmosis Syndrome

The entity termed presumed ocular histoplasmosis syndrome consists of a triad of findings: (1) discrete atrophic choroidal scars in the macula or midperiphery (“histo spots”), (2) peripapillary atrophy, and (3) choroidal neovascularization³⁷³ that can lead to loss of central vision.⁷¹ In contrast to the acute endophthalmitis¹⁴⁹ or choroiditis³⁰² that occurs as a manifestation of disseminated infection, the abnormalities seen with presumed ocular histoplasmosis syndrome occur in the absence of inflammatory changes in the vitreous or anterior chambers. Smoking, level of educational attainment, and older age have been reported as risk factors for acquisition of presumed ocular histoplasmosis among a cohort of affected adults.⁶⁸

Commonly diagnosed in endemic areas, the cause-and-effect relationship of the findings in presumed ocular histoplasmosis syndrome and histoplasmosis has been determined largely on the basis of a weak epidemiologic association with histoplasmin skin test reactivity.⁴² The clinical syndrome also occurs in persons residing in nonendemic regions, however.^{300,386,417} Little histopathologic evidence supports histoplasmosis as its cause.^{214,298,324} A single report detected *H. capsulatum* DNA in cells of an enucleated eye from an affected patient; however, a nonstandardized

polymerase chain reaction (PCR)–based methodology was used. Another isolated report of the ocular syndrome used a nested PCR assay to detect *H. capsulatum* in serum.¹⁷⁶ Presumed ocular histoplasmosis does not seem to occur in children younger than 10 years of age.⁴⁰⁵ A good recovery of vision has been reported to follow surgical removal of the choroidal neovascularization that accompanies this entity. Scleritis, a rare manifestation of histoplasmosis, has been reported in immunocompetent adults.⁸⁷

Illness Caused by Infection with *Histoplasma capsulatum* var. *duboisii*

In patients infected with *H. capsulatum* var. *duboisii*, focal lesions are seen more commonly in bones (usually the femur, ribs, or skull) and skin (cutaneous or subcutaneous).⁴ The lungs, gastrointestinal tract, liver, spleen, and lymph nodes rarely are involved. A progressive disseminated form of infection with *H. capsulatum* var. *duboisii* occurs and is associated with pyogranulomatous inflammation involving multiple organs.^{77,135,247,464} In addition, cases of isolated pulmonary histoplasmosis have been reported in immunocompetent persons years after departing an endemic region.^{333,336}

Radiographic Findings

The radiographic findings seen most commonly in children with histoplasmosis are not pathognomonic and may mimic the findings seen in tuberculosis or other granulomatous processes and, in some instances, neoplastic conditions, especially lymphoma.^{134,216,279,316} After small or moderate degrees of fungal exposure, the plain chest radiograph is normal in approximately 75% of skin test converters.^{151,458} Computed tomography (CT) is more sensitive and likely to reveal parenchymal infiltrates that are not visualized in plain radiographs. The most common pulmonary parenchymal changes are “soft” single or multiple, poorly defined areas of airspace consolidation,¹⁶³ often found in the basilar portions of the lungs. CT may also reveal a “reversed halo” sign.²⁵⁴ Findings either may fully resolve or consolidate into granulomas that persist, with or without calcification, in residents of, or travelers to, endemic areas.²⁹⁶

The appearance of enlarged hilar or mediastinal lymph nodes, either in association with pulmonary infiltrates or as isolated findings, also is a common radiographic finding in acute pulmonary histoplasmosis.³⁹⁰ Isolated hilar or mediastinal adenopathy occurs in 20% of cases, 80% of which are asymptomatic.⁸¹ With CT, low signal intensity within nodes sometimes is present; however, frank suppuration is unusual. Infected nodes may enlarge and compress or obstruct adjacent structures (Figs. 204.7A–B; see also Fig. 204.4). Nodes usually have reached their maximal size at the time of diagnosis and become smaller or return to normal in several months; calcification may occur, but not consistently. In infants and young children, clusters of small infiltrates occasionally coalesce into a larger bronchopneumonic lesion.¹⁵⁰ Although small pleural effusions are present in 10% of adults with acute histoplasmosis,⁴⁵³ they occur infrequently in children.^{2,325} Isolated calcifications may be seen in the spleen or liver months to years after infection. These calcifications result from the self-limited fungal dissemination that occurs during primary infection and often are appreciated as incidental findings in persons who have lived in or visited endemic regions.

Three distinct chest radiographic patterns have been described in persons who have had intense exposure to the fungus.¹⁵⁰ Persons from nonendemic areas initially may have scattered infiltrates that later evolve into “buckshot” calcifications. The second and most common pattern is the presence of smaller, nodular lesions. Finally, a diffuse miliary or interstitial pattern (Fig. 204.8) may occur, often in a patient with protective immunity. In PDH, the chest radiograph in adults may show abnormalities in only 25% to 50% of patients.⁸⁰ Diffuse abnormalities commonly appear during treatment of patients whose chest radiographs initially were normal.³⁵⁶ Diffuse interstitial or reticulonodular infiltrates are present in approximately 50%, and localized lesions are present in the remainder. In immunocompromised children, diffuse interstitial infiltrates are the most common radiographic findings; they worsen rapidly and in concert with progressive hypoxemia, especially in patients with HIV infection or patients receiving immunosuppressive therapy.⁸⁰ The presence of interstitial infiltrates at admission was reported in 60%

FIG. 204.7 Adolescent boy presenting with chest pain, difficulty in swallowing, fever, and weight loss. Upper mediastinal granuloma noted on (A) chest radiograph and (B) computed tomography scan of the chest.

of children with PDH of infancy in a Costa Rican series.²⁹³ Abdominal ultrasound evaluation or CT, or both, may show evidence of adrenal enlargement in chronic disseminated disease in adults.^{24,465}

Fibrosing mediastinitis caused by histoplasmosis is seen radiographically as pronounced thickening of the mediastinum that often compresses

TABLE 204.1 Laboratory Test Results in Children With Histoplasmosis According to Clinical Manifestations

Clinical Manifestation	Antigen ^a	Complement Fixation: antibody	Immunodiffusion: Antibody	Culture	Comments
Acute histoplasmosis with severe pulmonary disease (high inoculum)	++ ^b	++++	+++	+ ^c	Antigen assay results are likely to be positive early in the disease
Acute histoplasmosis with mild pulmonary disease	++	++++	+++	—	Antigen assay results are likely to be positive early in the disease
Acute histoplasmosis with fever >1 month	+++	++++	+++	—	
Mediastinal granulomas with or without associated symptoms and signs of compression	—	++	++	—	Middle mediastinal mass plus CF ≥1:32: biopsy not needed Histoplasmosis is the most likely cause
Disseminated disease, infants	++++	++++	++++	+++ ^c	
Disseminated disease, immunocompromised patient	++++	+++	++	+++ ^c	Serologic assay results may be negative early in the infection
CNS histoplasmosis	+	+++ ^d	++	—	
Pericarditis, erythema nodosum (other rheumatologic manifestations)	—	++	++	—	
Asymptomatic, history of histoplasmosis and/or presence of mediastinal calcified nodules, calcified hepatic or splenic nodules	—	+	+	—	

^aNegative antigen: progressive disseminated infection is unlikely.
^bSerum or urine, bronchoalveolar lavage fluid, or bronchial washings.
^cBone marrow and blood specimens.
^dAntibody detection in cerebrospinal fluid.
—, Negative; +, rarely positive; ++, occasionally positive; +++, frequently positive; +++++, always positive. CF, Complement fixation; CNS, central nervous system.

or obstructs the superior vena cava, major bronchi, esophagus, or other critical structures. It can be found in a localized pattern that frequently contains calcification. This condition must be differentiated from idiopathic fibrosis or fibrosis not induced by infection, which may cause similar symptoms.³⁶⁹ CT and magnetic resonance imaging help differentiate active inflammation from fibrosis and aid in monitoring progression.^{343,346} Diffuse mediastinal fibrosis caused by histoplasmosis is rare in children.

DIAGNOSIS

Several laboratory tests play key roles in establishing the diagnosis of histoplasmosis. Although each has value, optimal use necessitates an understanding of their differing sensitivities and specificities in various clinical settings.⁴²⁷ General guidelines for their interpretation are provided in Table 204.1.

Organisms Shown on Histology

In clinical and epidemiologic settings compatible with histoplasmosis, observation of 2- to 4-µm typical yeast forms¹⁶² in histopathologic specimens demonstrating granulomatous inflammation²⁷¹ is strong supportive evidence of histoplasmosis. Rarely, typical yeast may be observed but result from past infection.⁴²⁷ Care must be taken to differentiate *H. capsulatum* from the intracellular pathogens *Leishmania donovani* and *Toxoplasma gondii*, small variants of *Blastomyces dermatitidis*, endospores and young spherules of *Coccidioides immitis*, *P. marneffei*, and the yeast forms of *Cryptococcus neoformans*. Both Giemsa-stained and hematoxylin and eosin–stained specimens show intracellular yeasts in sputum, blood smears, bone marrow aspirates (Fig. 204.9), and biopsy specimens. The Gomori methenamine silver stain is the most sensitive reagent.²⁹⁴ Test sensitivity is better in disseminated forms of histoplasmosis, in which yeasts are readily observed in bone marrow, in affected tissue, and often in blood smears (Table 204.2).¹⁹⁷ Tests are less sensitive in self-limited primary infections,⁴⁶³ including acute pulmonary infection following heavy exposure, in which cytology and histopathology sensitivities are 25%.⁴²⁷

FIG. 204.9 Bone marrow aspirate from an immunocompromised girl presenting with a hemophagocytic-like syndrome with disseminated histoplasmosis illustrating intracellular yeast forms of *Histoplasma capsulatum*.

Histopathologic demonstration of typical yeast forms ranged from 18% to 62% in three large Indianapolis outbreaks.⁴²⁷ The technique usually is unrewarding in patients with calcified or fibrotic lesions.^{255,463}

Culture

Normally, sterile specimens and minced or homogenized tissue can be inoculated onto suitable media, such as brain-heart infusion agar, inhibitory mold agar, Sabouraud glucose (dextrose) agar, and enriched broth such as brain-heart infusion broth. The optimal method for recovery of *H. capsulatum* from blood is the lysis-centrifugation technique,²⁹⁷ which lyses white blood cells, inhibits complement, and prevents coagulation. After processing is completed, the resulting

TABLE 204.2 Sensitivity of Diagnostic Studies in Different Histoplasmosis Syndromes

Test	Acute Pulmonary	Subacute Pulmonary	Progressive Disseminated
Antigen (%)	75–81	19–34	91–92
Antibody (%)	40–80	78–89	63–81
Histopathology (%)	47	9–38	12–43
Culture (%)	34	9–15	75–85

Modified from Wheat LJ. Improvements in diagnosis of histoplasmosis. *Expert Opin Biol Ther.* 2006;6:1207–1221.

concentrate is transferred to culture media. Specimens from nonsterile sites should be cultured on media that inhibit bacteria and saprophytic fungi; non-cycloheximide-containing media also should be used to permit the growth of other opportunistic pathogens. Cultures are incubated aerobically at 25°C to 30°C and held for at least 12 weeks before being considered negative. Most isolates grow in 3 to 4 weeks.¹⁸² Use of the lysis-centrifugation system for blood culture has shortened the time required for identification of a positive culture result from approximately 16 days to 9 days.^{38,311} Laboratory-based rapid identification and differentiation of fungal pathogens using PCR methodology have been developed.^{128,323,326}

Recovery of *H. capsulatum* from a clinical specimen obtained from a symptomatic patient with a compatible illness confirms the diagnosis of active histoplasmosis. The only exception is the infrequent event in which an incidental granuloma is found to be culture positive, but active histoplasmosis is not a likely cause of the clinical symptoms. The sensitivity of culture varies in direct proportion to the severity of the infection and the fungal burden (see Table 204.2).⁴⁶² In primary acute, self-limited histoplasmosis, 40% of patients have positive culture results when samples are obtained from sputum (23%), bronchoalveolar lavage (BAL) fluid (39%), lung, and extrapulmonary sites (37%).⁴²⁷ In contrast, culture results are positive in 75% to 85% of adults with PDH. In the latter patients, sites from which *H. capsulatum* commonly is recovered include the lower respiratory tract, blood, bone marrow, CSF, liver, spleen, skin lesions, and synovium of affected joints.^{222,293} The highest yield in PDH is from bone marrow, which is positive in 75% of instances.^{357,422} Urine is positive in 40% to 70%, and sputum is positive in 60%.³⁷⁷ In adults with PDH, rates of positive lysis-centrifugation culture results in peripheral blood are 90% to 100% in acute dissemination and 50% in subacute dissemination; positive culture results are very rarely seen in chronic dissemination.

In forms of pulmonary histoplasmosis other than low-inoculum infection, sputum may be a reliable site for recovery of the organism in culture but not the best choice among diagnostic methods. High-inoculum infection after exposure to heavily contaminated sites usually results in moderate to severe infection in which patients seek medical attention within 2 weeks of exposure.⁶³ In these instances, the fungal burden is high, and specimens of respiratory secretions or lung tissue may show the organism, thus allowing the diagnosis to be made promptly. Culture results also may be positive, but the 2- to 4-week delay in achieving growth renders culture less desirable than other diagnostic methods, especially antigen detection. In adults with chronic cavitary pulmonary infection, sputum culture is positive in 50% to 85% of instances.^{151,425} The sensitivity of sputum culture may be increased with multiple sampling. Bronchoscopy with BAL may be helpful in patients with pulmonary disease. In a study of bronchoscopy in 71 adults, BAL results were positive in only 4% of patients with a single pulmonary nodule, but it increased to 55% in the remainder of the patient group. The highest yield of 88% occurred in the presence of infiltrates or cavitary disease.³²⁵ Bronchoscopy did not appear to be helpful in evaluating patients with adenopathy, chronic pleural effusion, or bronchopleural fistulas. In adults with mediastinal granuloma and fibrosis, culture results were positive in only 3.8% to 10%.^{103,245} In children, culture plus staining of BAL fluid has been rewarding in diagnosing high-fungal burden infection in patients with HIV, but it is less sensitive than lung biopsy

in other immunocompromised patients, especially those receiving chemotherapy for reticuloendothelial malignant disease. In patients with HIV infection, culture remains a value diagnostic tool with a positivity value of 75% compared with 35% in non-HIV-infected persons.²⁰

Culture results usually are negative in rheumatologic manifestations of histoplasmosis, such as arthritis, erythema nodosum, erythema multiforme, and pericarditis. The reason is presumed to be that these reactive manifestations usually occur months after low-burden infection in patients whose acquired cellular immune response has controlled fungal replication. Isolated CNS infection is uncommon in children, but meningitis was reported in 25 of 40 cases of PDH of infancy; yeasts were observed in the CSF, and *H. capsulatum* was recovered in culture from 4 patients.²⁹³ The number of organisms in CSF is small, so the yield is improved substantially by culturing large volumes (10–20 mL in adults) on at least two occasions.⁴⁵² In isolated CNS infections, culture is usually unrewarding.

Antibody and Antigen Detection

The serologic methods that are used most commonly for the diagnosis of histoplasmosis are immunodiffusion (ID) and CF. These tests are useful because, despite documentation of skin test reactivity in 50% to 70% of young, healthy adults residing in an endemic area, seropositivity in this population has been found to be 0.5% by ID and 2% by CF using the mycelial antigen and 4% with the yeast antigen. Therefore, if these test results are elevated, they serve to substantially increase the probability of acute or recent histoplasmosis when performed in a patient with a compatible illness.

Both serologic methods have equal sensitivity (75–85%); however, ID is slightly more specific (>95% vs. 85–90%).^{422,423} In immunocompetent patients, either or both tests are positive in 95% of patients with acute primary pulmonary infection. CF titers often become positive 2 to 4 weeks earlier, usually within 4 to 6 weeks after exposure.⁴²² In patients with CF antibody, 25% have a negative ID result; only 1% of patients reactive by ID are CF negative.⁹¹ When the ID test is reactive, however, it remains so for a longer period of time. In addition to the 4- to 6-week lag in developing elevated titers, an important limitation of both serologic assays is their reduced sensitivity in immunosuppressed patients. Only 50% of immunosuppressed children and adults with disseminated histoplasmosis are seropositive.⁹¹ Of immunocompetent infants and young children with severe PDH during infancy and early childhood, 93% had elevated antibody titers.²⁹³

Cross reactivity with other fungal antigens affects CF and ID assays.⁴⁴² CF cross reactivity occurs most commonly with *B. dermatitidis* (40%) and *C. immitis* (16%). Cross reactions also occur, albeit rarely, with candidiasis, tuberculosis, aspergillosis, and cryptococcosis.^{249,443,258} Cross reactivity also is seen occasionally in patients with chronic cavitary tuberculosis, although simultaneous infection with tuberculosis and fungal pathogens can occur.^{132,443} Variability in the specificity of commercial reagents has been reported to cause false-negative results.²³²

Complement Fixation

CF uses sensitized sheep red blood cells, killed whole *H. capsulatum* yeast cells, and histoplasmin, a soluble mycelium-form filtrate antigen. In a common-source outbreak of acute primary pulmonary histoplasmosis, the titer becomes positive in 6% of individuals at 3 weeks, 73% at 4 weeks, and 77% at 6 weeks.^{91,443} Upon resolution of infection, titers decrease to 1:8 to 1:16 within 4 to 6 months and, in most instances, become undetectable (<1:8) by 9 months. Reported sensitivities for a single titer vary from 70% to 95% and depend on the threshold for considering a result positive. Single titers of 1:32 or greater performed by an experienced laboratory are strong supportive evidence of acute or recent infection, especially when the accompanying clinical symptoms are compatible. One report showed that 12 of 28 patients with non-*Histoplasma* febrile pneumonia had false-positive CF titers of 1:32 or greater, so other laboratory and clinical data need to be considered.³⁹⁶

The demonstration of a fourfold increase between acute and convalescent sera provides the best serologic evidence of recent infection. The individual yeast (CF-Y) and mycelial (CF-M) phases can be measured.

The CF-Y phase is more sensitive than the CF-M phase when performed in recent or active infection. In a series of 11 children with acute pulmonary histoplasmosis, CF-Y was 1:32 or greater in nine children, but the CF-M titer was 1:32 or greater in only three children. In highly endemic areas, background low-titer CF serologic reactions may be present in 5% to 15% of adults but they have been reported to occur in as many as 30%.^{141,150,444}

The serologic response seems to correlate with the severity of disease in immunocompetent individuals with acute infection.^{226,447} During an extensive outbreak of histoplasmosis, seropositivity was 90% to 100% in severe acute histoplasmosis, 86% in moderate histoplasmosis, 75% in mild histoplasmosis, and 18% in asymptomatic histoplasmosis. Twenty-five percent of patients with acute histoplasmosis have CF titers that could be considered borderline positive, between 1:8 and 1:16.⁹¹ Although they may result from previous infection, these titers should not be disregarded if clinical symptoms are compatible with acute infection. In adults with chronic pulmonary histoplasmosis, the CF titer is greater than 1:32 in almost all patients.^{134,210,279} In children who present with middle mediastinal masses caused by histoplasmosis, 67% have CF titers of 1:32 or greater.¹³⁴ A newer enzyme immunoassay that measures *Histoplasma* IgM and IgG antibodies appear to have demonstrable higher sensitivity than CF and ID.³³⁷

The serologic diagnosis of patients with isolated meningitis caused by *H. capsulatum* often is problematic because no single test exhibits high sensitivity.⁴⁵² CF and ID can be positive in CSF, but half of patients with other chronic fungal meningeal infections may show false-positive results.^{320,442} CF-M antibody seems to be the most sensitive and specific test for the diagnosis of meningitis caused by histoplasmosis. In one study, no false-positive CSF CF-M titers occurred in patients with cryptococcal meningitis but CF-Y was false positive in five of 18 patients.⁴⁴² Individuals with fibrosing mediastinitis or mediastinal granuloma generally have negative or very low levels of CF antibody.⁴⁴⁷

Immunodiffusion

The micro-ID method detects precipitins (reported as bands) against the H and M glycoprotein antigens of *H. capsulatum*.⁴⁴⁴ The M band is present in 25% of infections by the fourth week of infection and in 50% to 86% by the sixth week.^{30,91,315} It can persist for 18 to 36 months after recovery, but eventually it becomes nonreactive. In endemic areas, in which serologic surveys show that 24% of healthy adult blood donors have CF-Y titers of 1:8 or 1:16, ID serologic test results are positive in less than 1%.¹⁴¹ Because it is more specific, ID can be of value to confirm the diagnosis of histoplasmosis in patients with *Histoplasma* CF titers in the borderline 1:8 to 1:16 range.⁴¹⁶

The H band is present infrequently in patients with histoplasmosis; when seen, it is transient, and its presence suggests active infection.¹⁵⁰ In patients with active pulmonary histoplasmosis, one-half to three-fourths have an M band alone. The H band only is present in 10% to 20% of acute infections,⁴⁴⁴ and only 10% of patients have both M and H bands present. The presence of both is highly suggestive of active histoplasmosis. The H band is detected less consistently in children with histoplasmosis.⁴¹⁹ In adults with disseminated disease, both bands are present in 25% of patients. The M band has been detected in 52% and 57% of patients with chronic pulmonary and disseminated disease.¹⁵⁵ The ID test is not approved for use in CSF specimens and has not been evaluated as a test for the diagnosis of meningitis.⁴²⁷

Antigen Detection

The development in 1986 and further refinements of the *Histoplasma* antigen assay have filled an important gap in laboratory diagnosis.⁴⁴⁸ When performed on serum, urine, or other selected body fluids, antigen detection provides rapid, accurate, noninvasive diagnostic information for the most serious manifestations of disease. It is especially useful for the evaluation of infections in immunocompromised hosts, in whom serologic methods often produce negative results. Although evaluated almost exclusively in adults, antigen detection occupies the same diagnostic niche for managing infection during infancy and childhood.

Antigen detection is most sensitive in infections accompanied by high fungal burdens.⁴⁶² These include progressive disseminated infections in intensely exposed or immunocompromised hosts and primary

pulmonary infection, in which antigen detection reflects the early hematogenous dissemination that occurs before being aborted by an effective cellular immune response. In addition to its usefulness in diagnosis, antigen assay provides a quantitative parameter with which to assess the pace and adequacy of response to therapy and, thereafter, a sensitive monitor that promptly detects relapse in patients who are at high risk for recurrence.^{433,437-439}

The sensitivity of urine antigen detection (see Table 204.2) in patients with acute primary pulmonary infection is 75% to 81%, with the highest rates seen in patients tested within a few weeks of exposure, in those with large inoculum exposure, and in patients with extensive pulmonary involvement.^{425,463} Sensitivity is less in subacute pulmonary and chronic cavity infection in adults. The sensitivity of antigen detection is very high in manifestations of progressive disseminating manifestations of histoplasmosis. In adults with disseminated infections, antigen is detected in 91% to 92% of immunosuppressed and nonimmunosuppressed patients and in 95% to 100% of patients with AIDS.^{448,449,463} In 22 children with PDH, urinary antigen test results were positive in 100%.¹²⁵

Although *Histoplasma* antigen can be detected in serum, the sensitivity is substantially less than that of urine. In immunosuppressed adults with disseminated histoplasmosis, antigen was detected in 50% of serum samples and in 92% of urine specimens. Similarly, in patients with disseminated histoplasmosis complicating AIDS, antigenuria was seen in 95% versus 85% in serum.^{448,463} Antigen often is found in BAL fluid of patients after high-inoculum exposure to histoplasma spores and in immunocompromised patients with hematogenous dissemination and lung involvement.^{436,440}

In adults with isolated meningitis, antigen detection in CSF may be the sole basis for confirming the diagnosis.^{448,449,452} The range of antigen positivity in all cases of meningitis is 40% to 66%; the highest rates are found in severe infections with heavy fungal burdens, especially infections that occur in immunosuppressed patients.⁴⁵² In patients with clinical findings suggestive of meningitis but with no antigen present in CSF, antigen detected in extrameningeal sites sometimes can confirm the diagnosis.

Antigen concentration decreases during effective therapy.¹⁶⁸ Failure of the antigen concentration to decline or documentation of progressive increase may indicate treatment failure. Persistent but decreasing concentrations of antigenuria may be present after completion of an appropriate and effective course of antifungal therapy. Patients who have completed appropriate courses of therapy for serious infections and have had resolution of their clinical symptoms yet demonstrated persistent but decreasing concentrations of antigenuria have done well after the completion of the planned course of antifungal therapy. Infants with PDH who have been treated adequately, who have had a good clinical response, and whose urine antigen levels have substantially decreased during therapy often have persistence of low levels of urine antigen after completion of amphotericin B therapy.³²⁸ Residual excretion of urine antigen after adequate treatment continues to decrease and eventually ceases; monitoring is recommended to confirm resolution of antigenuria.^{125,328}

Conversely, the persistence of moderate antigenuria has been associated with a risk for recrudescence. This risk has been shown best, but not exclusively, in patients with AIDS and histoplasmosis, in whom significant antigenuria often persists after cessation of therapy.^{437,438} Monitoring urine antigen in such patients has shown that increasing concentrations foretell recurrence of active infection.⁴³⁷ The sensitivity of the antigen assay is high, however, and the pattern of antigen clearance has not been established firmly in other clinical settings.

Antigen concentrations in urine measured with a quantitative assay often exceed the upper end of the calibration curve, especially in disseminated infections. If urine concentration is too high and unable to quantitate, monitoring is more informative if antigen concentrations of serum are initially followed because concomitant serum concentrations are lower than those of concomitant urine samples and are more likely to be within the range in which differences in concentration could be measured accurately. Thereafter, when antigenemia is resolved, urine concentrations can be followed with the quantitative assay. Testing should be performed routinely at 3- to 4-month intervals during treatment, at the end of therapy, if symptoms recur, and periodically for another year to monitor for relapse.

Cross reactions in the *Histoplasma* antigen assay occur in paracoccidioidomycosis, African histoplasmosis caused by *H. capsulatum* var.

duboisii, blastomycosis, sporotrichosis, and infections caused by *P. marneffei*.⁴⁵⁷ Because these infections have distinguishing epidemiologic and clinical features and because supportive diagnostic tests may aid further in differentiating them from histoplasmosis, such cross reactions usually create little difficulty in interpreting positive test results.

Skin Testing

A skin test for histoplasmosis that uses a standardized histoplasmin antigen prepared from a mycelial phase culture filtrate had been a valuable epidemiologic and investigational tool but provided limited diagnostic usefulness for distinguishing past from active infection; it no longer is commercially available.^{131,150}

Molecular Methods

Epidemiologic studies have used restriction fragment length polymorphisms of DNA. Nucleic acid–based and genome-wide approaches have been used to explore the genetic diversity of the pathogen.^{213,273,414} Molecular methods also have been used to examine strains recovered from patients with failed therapy and to identify relatedness in isolates recovered after organ transplantation.^{235,450}

Molecular methods that reliably detect *H. capsulatum* in clinical samples are starting to show promise when compared with standard diagnostic tests.^{67,276} PCR methodology has been evaluated for identifying *H. capsulatum*²⁶ in tissue and body fluids, but false-negative results were encountered in one-third of specimens.³⁷ PCR methodology used with clinical specimens (urine, serum, BAL, CSF) containing urine antigen showed specificities of 80% to 100% but sensitivities of only 0% to 22%.⁴²⁶ More recent reports show promise for PCR methodology in laboratory identification of *H. capsulatum* in clinical samples.^{26,128,354,371}

TREATMENT

Most patients with symptomatic histoplasmosis recover without receiving antifungal therapy.¹⁵⁰ Treatment is required for patients with severe symptoms, prolonged illness, congenital or acquired immune dysfunction,

or signs or symptoms suggestive of progressive dissemination. Evidence-based, consensus practice guidelines for treatment of histoplasmosis have been published and include recommendations for treatment of children.⁴⁴¹

No controlled therapeutic trials have been conducted in children. Chronic pulmonary infection and subacute and chronic dissemination syndromes rarely occur in children. Recommendations for treating the clinical manifestations of histoplasmosis seen most frequently in children are summarized in Table 204.3. These recommendations have been derived from anecdotal published reports, clinical experience, and extrapolation from experience in adults.

Medical Management for Manifestations Requiring Antifungal Therapy

Because most patients with light or moderate exposure to fungal spores recover without treatment, the first decision is to determine whether to observe the patient carefully or to begin administering an antifungal agent. The key criteria in making this decision are clinical assessment of the character, severity, and duration of symptoms and assessment of the adequacy of the patient's cellular immunity. When treatment with antifungal agents has been elected, a regimen is selected that is appropriate for the initial findings. Manifestations of histoplasmosis in children that most often require antifungal treatment are severe or protracted symptoms resulting from acute primary pulmonary infection, mediastinal adenitis that is causing compression of adjacent structures, disseminated infection of infancy, and infection in an immunocompromised host. Treatment recommendations are summarized in Table 204.3.

The antifungal agents that play primary roles in medical management include amphotericin B deoxycholate, liposomal amphotericin B, amphotericin B lipid complex, and itraconazole. Amphotericin B preparations are fungicidal for *H. capsulatum*, whereas itraconazole is fungistatic. Combined use of the two agents does not result in synergy. On the basis of its faster clearance of fungemia in patients with AIDS,^{199,431} amphotericin B is more effective for severe infection than

TABLE 204.3 Summary of Treatment Recommendations for Children With Histoplasmosis

Manifestation	Moderately Severe or Severe Illness	Mild to Moderate Illness
Acute pulmonary manifestations	AMB ^a for 1–2 wk followed by ITR ^b for 12 wk Steroids appears to be beneficial in patients with high-inoculum disease	Symptoms <4 wk: none Persistent symptoms >4 wk: ITR for 6–12 wk ^b Alternative agents: FLU, POS ^b
Disseminated disease (non-HIV)	AMB ^b for 1–2 wk followed by ITR for at least 6 mo ^c	ITR for 6–18 mo or the same as for severe illness ^b Alternative agents: FLU, POS ^c
Disseminated disease (HIV)	LAB for 1–2 wk followed by ITR for life	
CNS histoplasmosis	LAB for 4–6 wk, followed by ITR for 12 mo ^b	
Granulomatous mediastinitis	AMB ^a , then ITR for 6 mo	ITR for 6–12 mo Alternative agents: fluconazole and posaconazole ^c
Fibrosing mediastinitis	ITR for 3 mo ^d	Same as for severe illness
Pericarditis	Pericardial drainage for severe tamponade + an NSAID, for 2–12 wk ^e	NSAID 2–12 wk
Rheumatologic manifestations	NSAID for 2–12 wk	Same as for severe illness
Compression of contiguous structures by granulomatous lymphadenopathy	No treatment needed if symptoms <4 wk Symptoms >4 wk: ITR for 6–12 wk, ^{f,g}	

^aLAB or deoxycholate AMB. Many clinicians prefer LAB because it has a lower frequency of infusion-related adverse reactions and nephrotoxicity. Dosages: LAB: 3–5 mg/kg body weight, IV once daily; deoxycholate AMB: 0.7–1.0 mg/kg body weight, IV once daily.

^bITR drug level monitoring is needed. ITR suspension has higher bioavailability than the capsule form and is the preferred agent for follow-up ITR treatment. Dosages: FLU: 5–6 mg/kg body weight IV or PO per dose twice daily (max, 600 mg/day); ITRA: initial loading dose of 2.5–5 mg/kg body weight (max, 200 mg) per dose PO three times daily for first 3 days of therapy followed by 2.5–5 mg/kg body weight (max, 200 mg) per dose twice daily; POS: oral suspension, 400 mg twice daily (children ≥8 y).

^cSerum concentrations of posaconazole should be monitored and achieve a level of ≥1 µg/mL at steady state.

^dTherapy should continue until the *Histoplasma* antigen concentration in serum is undetectable and the *Histoplasma* urine antigen concentration is <2 µg/mL and stable. (Low urine concentrations can be present for extended periods following successful therapy.)

^eProbably ineffective if fibrotic. When granulomatous mediastinitis could be present, it may be considered.

^fIndomethacin is the preferred NSAID. Prompt administration may obviate need for drainage in non-life-threatening manifestations of pericarditis.

^gSteroids may be beneficial in reducing the effect of compression. If steroids are used, ITR should be used.

AMB, Amphotericin B; CNS, central nervous system; FLU, fluconazole; HIV, human immunodeficiency virus; ITR, itraconazole; IV, intravenously; LAB, liposomal amphotericin B; max, maximum; NSAID, nonsteroidal antiinflammatory agent; PO, orally; POS, posaconazole.

Modified from Wheat LJ, Freifeld A, Kleiman MB, et al. Practice guidelines for management of patients with histoplasmosis. *Clin Infect Dis*. 2007;45:807–825.

is itraconazole.⁴⁴⁵ Amphotericin B is used most commonly as “induction” therapy, especially in severe infections; after substantial clinical improvement has occurred, the drug is stopped, and itraconazole is begun to complete treatment. Monotherapy with itraconazole is effective for treating patients who have mild or only moderately severe symptoms. In addition to regimens that are used to treat acute infections, suppressive (secondary prophylaxis) regimens have been developed for treating patients with AIDS because of the high rate of relapse if antifungal treatment is stopped and if immune function has not been improved by HAART.⁴⁴¹ Primary prophylactic regimens also have been developed for use by patients with AIDS who live in highly endemic areas.²⁶¹

A detailed discussion of the antifungal agents used to treat histoplasmosis is presented in Chapter 240. Amphotericin B deoxycholate usually is well tolerated and effective in children. Liposomal amphotericin B is the best evaluated of the lipid preparations. A comparative trial of amphotericin B deoxycholate and liposomal amphotericin B in adults with disseminated histoplasmosis and AIDS showed faster improvement and lower mortality rates with the liposomal preparation.¹⁹⁹

For moderately severe or severe infections amphotericin B is administered for 1 to 2 weeks. This regimen is always followed by a course of itraconazole (see Table 204.3).⁴⁴¹ Because relapse has been observed in immunosuppressed patients, close follow-up with monitoring of urine antigen concentrations is required.

Itraconazole generally is well tolerated by children and, in adults, is more effective and less likely to induce resistance than the other azoles. Although formal trials using itraconazole have not been conducted in children, clinical experience has confirmed its effectiveness as the oral azole of choice. The erratic bioavailability of the capsule form can be improved when it is taken with liquids with low pH and caloric content (concomitant food and a cola drink are recommended).¹⁹² Serum levels should be monitored, particularly if symptoms persist.¹⁴⁴ The liquid solution of itraconazole is better absorbed, particularly when it is taken on an empty stomach, but it may have adverse gastrointestinal effects that affect compliance. The 90% minimal inhibitory concentration (MIC₉₀) of itraconazole for *H. capsulatum* is less than 0.01 µg/mL; the optimal therapeutic level has not been determined, but serum concentrations greater than 2 µg/mL are effective, readily achieved, and well tolerated.¹⁷⁴ With the drug's long half-life, serum concentrations vary little after steady state is achieved (approximately 2 weeks). When used as monotherapy or as step-down treatment after amphotericin B induction, a loading dose of itraconazole consisting of 150% of the total daily dose is recommended for the initial 3 days of therapy. As with the other azoles, important drug-drug interactions need to be considered in patients receiving agents known to affect excretion of the azole or whose excretion is affected by the antifungal agent.

Fluconazole was less effective than itraconazole in treating adults with chronic pulmonary histoplasmosis²⁶¹ or disseminated histoplasmosis.⁴⁵⁰ It also has been associated with relapse in disseminated infection,⁴⁵¹ is less effective than itraconazole for secondary prophylaxis in adults with disseminated infection,²⁶⁴ and clears fungemia more slowly in adults with disseminated infection than does itraconazole.⁴³³

With the availability of newer azoles with high efficacy and improved safety profile, ketoconazole is no longer a recommended agent for the treatment of histoplasmosis.

Both voriconazole and posaconazole have in vitro activity against *H. capsulatum*. Posaconazole has shown greater activity,^{82,435} and it seems to be more active in experimental models and several case reports. Six patients with severe forms of histoplasmosis (five with disseminated disease) received salvage treatment with posaconazole, all with favorable outcomes.³³⁵ Resistance that seems to have been induced by fluconazole when the drug was used in patients with AIDS also was accompanied by an increase in MIC values to voriconazole, a finding suggesting that resistance may emerge during treatment with voriconazole.^{435,434} However, a review of isolates from 208 cases found no development of drug resistance during a 4-year period.⁴⁴ Voriconazole and posaconazole have been effective in isolated reports describing differing manifestations of infection.^{6,102,127,148,181,280,335,402} These agents and fluconazole remain second-line alternatives to itraconazole.^{73,318} If these agents are elected for use, therapeutic drug monitoring is recommended.

Primary Pulmonary Infection

Primary pulmonary histoplasmosis that occurs after exposure to a large inoculum of spores may result in life-threatening illness.^{110,151,150,166} Infection of this severity should be treated promptly; induction with amphotericin B is indicated and it is continued until substantial clinical improvement occurs. Anecdotal evidence indicates that concomitant use of corticosteroids may be beneficial in treating patients with severe inhalation and adult respiratory distress syndrome.^{209,395,473} After improvement resulting from amphotericin B induction, itraconazole should be started and continued for at least 3 months. In patients who may not appear as ill, but with laboratory or clinical evidence suggestive of progressive primary dissemination, empiric therapy should be initiated.

Patients without respiratory distress but whose systemic complaints, such as fever, fatigue, and weight loss, persist for 2 to 4 weeks or longer also are candidates for antifungal therapy. In these instances, firm criteria to guide the timing of this decision are not established, and treatment must be individualized. Nonetheless, as observed when amphotericin B was the only effective treatment, and its toxicity and inconvenience resulted in deferring its use for longer than currently practiced, a significant proportion of these symptoms could be expected to undergo spontaneous resolution. The convenience of oral administration of antifungal agents renders the decision less problematic because these protracted but mild to moderately severe symptoms may be treated with itraconazole. Itraconazole should be used for at least 6 weeks in these instances (see Table 204.3).

Mediastinal Adenitis
